EXECUTIVE SUMMARY

This report presents the results of the investigation performed by Parsons Engineering Science, Inc. (Parsons ES) at Bolling Air Force Base (AFB), District of Columbia to evaluate the use of intrinsic remediation (natural attenuation) with longterm monitoring (LTM) as a remedial option for dissolved benzene, toluene, ethylbenzene, and xylene (BTEX) contamination in the shallow saturated zone. Parsons ES conducted field investigations during August 1994 and June 1996 at the former Car Care Center Site (Building 41). The source of the contamination was leaking underground storage tanks and other associated equipment. BTEX and total volatile hydrocarbons (TVH) was determined to be dissolved in groundwater and adsorbed to soils. Residual light nonaqueous phase liquid (LNAPL) was found throughout the soil column, both above and below the groundwater interface. However, minimal mobile LNAPL (free product) was observed at the site during the field investigations. This study focused on the impact of the dissolved BTEX and residual LNAPL on the shallow groundwater system at the site. Potential electron acceptors were analyzed to quantify ongoing biodegradation. Site history and the results of soil and groundwater investigations conducted previously are also summarized in this report.

An important component of this study was an assessment of the potential for contamination in groundwater to migrate from the former Car Care Center Site (Building 41) to potential receptors. The Bioplume II model was used to estimate the rate and direction of dissolved BTEX movement through the shallow saturated zone under the influence of advection, dispersion, sorption, and biodegradation. Input parameters for the Bioplume II model were obtained from data collected by Parsons ES during August 1994. Extensive site-specific data were used for model calibration and implementation. Model parameters not measured at the site were either obtained from previous site characterization data or supplemented using established literature values for similar aquifer materials.

The groundwater sampling activities and analytical results from both the August 1994 and June 1996 sampling events suggest that natural attenuation mechanisms are occurring at the site. Fate and transport modeling results suggest that dissolved BTEX contamination present in groundwater poses no significant risk to human health or the environment in its present, or predicted future, concentration and distribution. The Air Force therefore recommends that intrinsic remediation with LTM be implemented for dissolved BTEX contamination found in groundwater at the former Car Care Center Site (Building 41). To enhance these natural processes, the Air Force also recommends installation of a soil vapor extraction (SVE) system. Under this treatment alternative, the Air Force Center for Environmental Excellence (AFCEE) will provide a specialized computer-controlled internal combustion engine (ICE) system to power the SVE system. The ICE system provides off-gas treatment due to the combustion process. Because the ICE system is costly to operate over extended time periods, the system would be converted to a bioventing system once BTEX concentrations in the soil gas are reduced.

The Air Force recommends using four LTM wells to verify Bioplume II model predictions and to monitor long-term migration and degradation of dissolved BTEX. Also, three point-of-compliance (POC) monitoring wells are recommended to establish a compliance boundary for the site. In order to monitor effectiveness of the intrinsic remediation program, these wells should be sampled on a semiannual basis for at least 11 years. If the data collected during this period supports the anticipated effectiveness of intrinsic remediation, the sampling frequency can be reduced to once every year. The groundwater samples should be analyzed for BTEX compounds by USEPA Method SW8020. If BTEX concentrations in groundwater from the POC wells exceed the District of Columbia's target cleanup levels of 5 microgram per liter (μ g/L) for benzene, 1,000 μ g/L for toluene, 700 μ g/L for ethylbenzene, or 10,000 μ g/L for total xylenes, additional corrective actions may be required to remediate groundwater at the site.

SECTION 1

INTRODUCTION

Parsons Engineering Science, Inc. (Parsons ES) prepared this Engineering report to evaluate the use of intrinsic remediation (natural attenuation) for remediation of fuel-hydrocarbon-contaminated groundwater at the Car Care Center, Bolling Air Force Base (AFB), District of Columbia (DC). Previous investigations determined that gasoline had been released into the soil and shallow groundwater at the site. The main emphasis of the work described herein was to evaluate the potential for naturally occurring degradation mechanisms to reduce dissolved fuel-hydrocarbon concentrations in groundwater to levels that are protective of human health and the environment.

1.1 SCOPE AND OBJECTIVES

Parsons ES was retained by the United States Air Force Center for Environmental Excellence (AFCEE) to conduct site characterization and groundwater modeling in support of intrinsic remediation with long-term monitoring (LTM). Intrinsic remediation is a risk management strategy that relies on natural attenuation to control exposure to contaminants in the subsurface. The scope of work for this project involved the following tasks:

- Reviewing existing hydrogeologic data and soil and groundwater quality data for the site;
- Conducting supplemental site characterization activities to determine the nature and extent of soil and groundwater contamination and to collect geochemical data in support of intrinsic remediation;
- Developing a conceptual hydrogeologic model of the shallow saturated zone, including the current distribution of contaminants;
- Determining whether naturally occurring degradation processes are occurring in site groundwater;
- Designing and setting up the Bioplume II model for site hydrogeologic conditions;
- Performing sensitivity analyses with a range of model input parameters to ensure that several contaminant fate and transport scenarios are considered;
- Determining whether naturally occurring processes are sufficient to minimize benzene, toluene, ethylbenzene, and total xylene (BTEX) plume expansion so that

groundwater quality standards are met at a downgradient point of compliance (POC);

- Conducting a preliminary exposure pathway analysis for fuel hydrocarbon contamination in groundwater;
- Developing remedial action objectives (RAOs) and reviewing available remedial technologies;
- Using model results to recommend the most appropriate remedial option based on specific effectiveness, implementability, and cost criteria; and
- Providing a LTM plan that includes POC wells, and a sampling and analysis plan.

During August 1994, Parsons ES and the United States Army Corps of Engineers (USACE) performed site characterization activities for the intrinsic remediation investigation. The activities consisted of cone penetrometer testing (CPT) in conjunction with laser-induced fluorometry (LIF) using the USACE's cone penetrometer truck. Initially, site lithology using CPT, and the extent of the light nonaqueous liquid (LNAPL) plume using LIF, were determined during concurrent pushes. These data determined the need for additional groundwater sampling locations. Permanent and temporary monitoring points then were installed to characterize the site hydrogeology and groundwater geochemistry and to further define the contaminant plume. Parsons ES then performed groundwater, LNAPL, and soil sampling activities utilizing the previously existing wells and newly installed monitoring points.

Bioplume II and site-specific data were used to develop a contaminant fate and transport model for the site. Using the results of the model, a preliminary exposure pathway analysis was performed. As part of the Engineering Evaluation/Cost Analysis (EE/CA), this modeling effort had three primary objectives: 1) to predict the future extent and concentration of a dissolved contaminant plume by modeling the combined effects of advection, dispersion, sorption, and biodegradation; 2) to assess the possible risk to potential downgradient receptors; and 3) to provide technical support during regulatory negotiations for intrinsic remediation with LTM, as appropriate.

Several remedial options were evaluated during this EE/CA, including mobile LNAPL removal, groundwater extraction and treatment (i.e., pump and treat), soil vapor extraction (SVE), bioventing, biosparging, and natural contaminant attenuation with LTM. Hydrogeologic and groundwater chemical data necessary to evaluate the various remedial options were collected under this program. However, the field work conducted under this program was oriented toward the collection of hydrogeologic data to be used as input into Bioplume II and to support intrinsic remediation.

This report contains nine sections, including this introduction, and six appendices. Section 2 summarizes site characterization activities. Section 3 summarizes the physical characteristics of the study area. Section 4 describes the nature and extent of soil and groundwater contamination and the geochemistry of soil and groundwater at the site. Section 5 describes the conceptual model developed for the site, Bioplume II model assumptions and input parameters, sensitivity analyses, model output, and the

results of the Bioplume II modeling. Section 6 describes remedial alternatives evaluation criteria and presents a comparative analysis of selected options. Section 7 presents the LTM plan for the site. Section 8 presents the conclusions of this work and provides recommendations for further work at the site. Section 9 lists the references used to develop this document. Appendix A contains boring logs and well completion diagrams. Appendix B presents groundwater elevation and LNAPL thickness data. Appendix C contains soil and groundwater analytical results. Appendix D contains gridded model input parameters and model calibration results. Appendix E contains a diskette of the Bioplume model input and output data in ASCII format. Appendix F contains the costing worksheets and present worth calculations developed during the comparative analysis of selected remedial options.

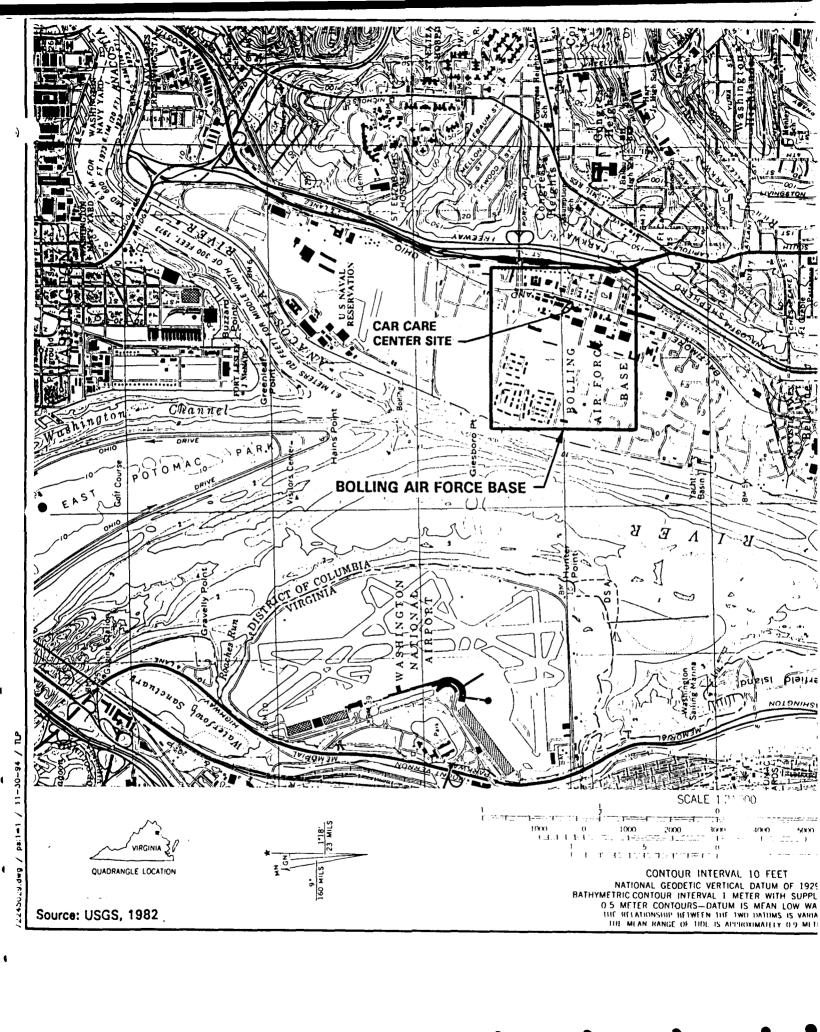

1.2 FACILITY BACKGROUND

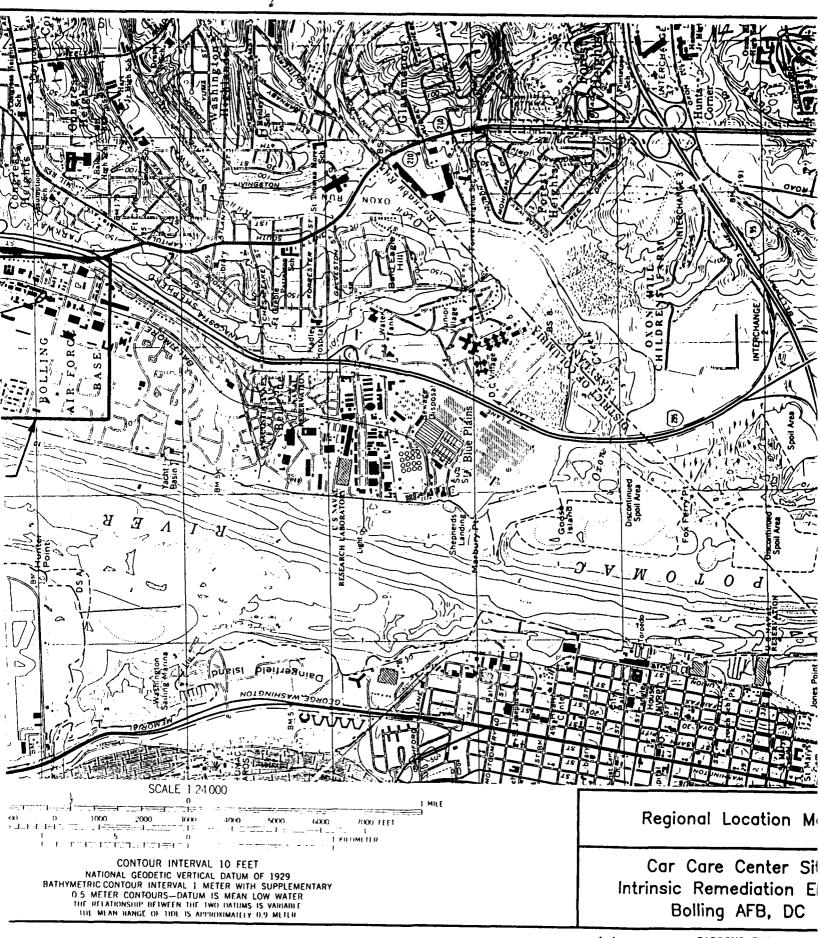

Bolling AFB is located at 38° 51'N latitude, 77° 01'W longitude in the inner margin of the Atlantic Coastal Plain Physiographic Province. The base is located in the southern portion of Washington, DC near the confluence of the Potomac and the Anacostia Rivers. The Car Care Center, Building 41 (ST-04), is located on the eastern side of Bolling AFB approximately 2,500 feet east of the Potomac River. Bolling AFB comprises approximately 620 acres of land including annexes, easements, and leased property. Most of the area surrounding Bolling AFB is highly developed urban properties. Bolling AFB is bordered on the north by Anacostia Naval Air Station. The southern property line is bordered by the Navy's Bellevue Housing Annex and the Naval Research Laboratory. The apparent groundwater flow direction is toward the Potomac River. Figure 1.1 is a regional location map showing the position of Bolling AFB relative to the surrounding area.

For the purposes of the work described herein, the Car Care Center Site at Building 41 (ST-04) includes the property of the Car Care Center, and the adjacent properties that contain monitoring wells. This area includes Building 13, Building 503, Building 518, and the parking lot across Brookley Avenue. The following sections describe the previous and current uses of the Car Care Center Site. Figure 1.2 is a site map showing the Car Care Center Site and surrounding features of the base.

1.2.1 Operational History

The Car Care Center served as an auto repair and fueling facility for Bolling AFB from 1936 to 1982. It ceased gasoline fueling operations in 1982 (Baker, 1994) when the site's underground storage tanks (USTs) were taken out of service. At the time of this remedial investigation, the facility provided automobile maintenance services as its primary function. The Car Care Center recently moved to a new location on the Base. As a result, the Car Care Center Site is no longer functioning as a service station. The Car Care Center (Building 41) utilized several USTs for the storage of gasoline and waste oils. Two former 12,000-gallon gasoline USTs located near the southeast corner of the Car Care Center facility (Figure 1.3) were removed in 1983. The remaining 12,000-gallon gasoline UST was located near the northeast corner of the facility. Baker Environmental, Inc. removed this UST during the week of 8 August 1994. Four 275-gallon USTs were used on the property for the storage of waste oils. The waste oil USTs were abandoned in place during the early 1980s and removed in 1995.

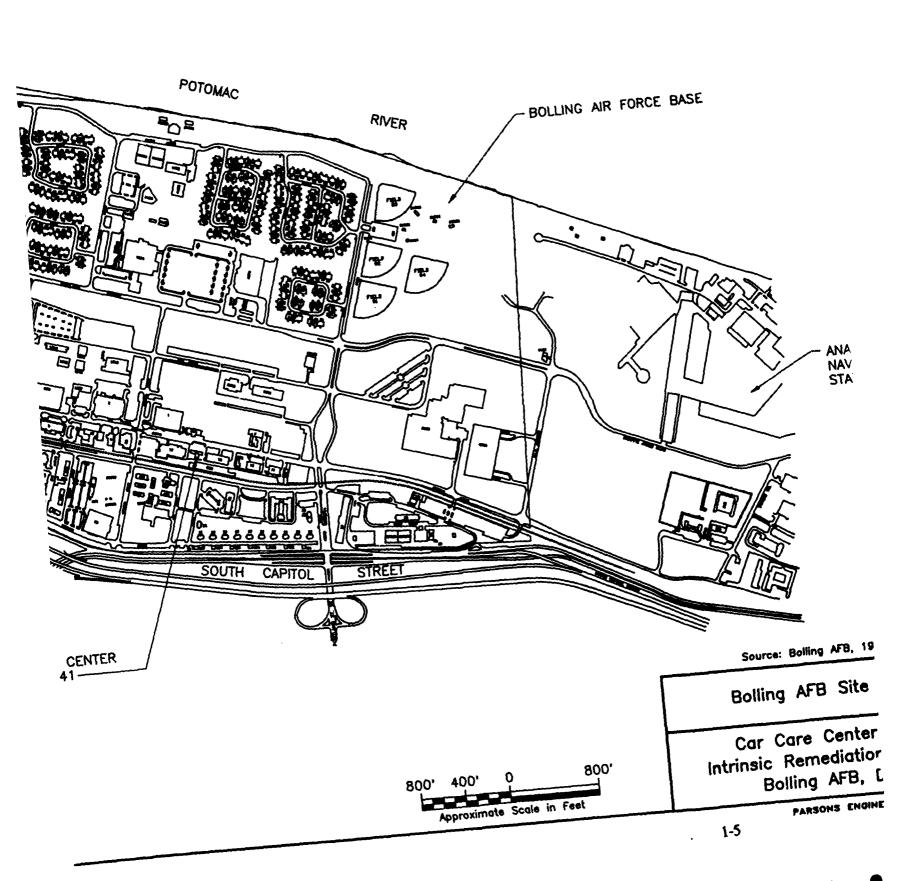

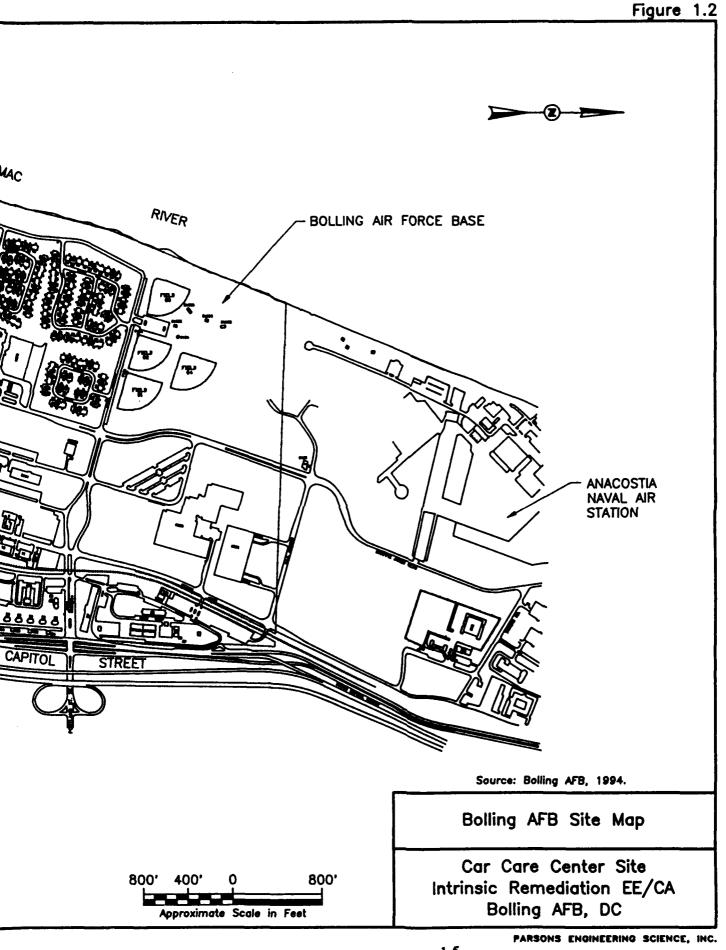

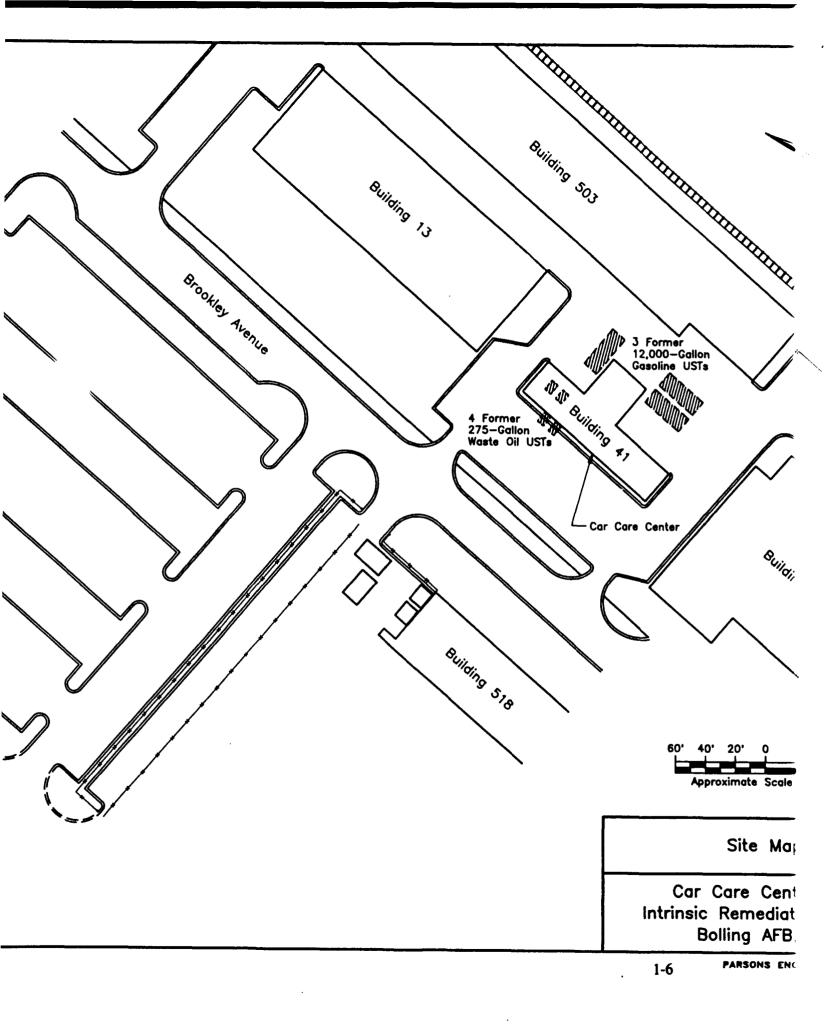

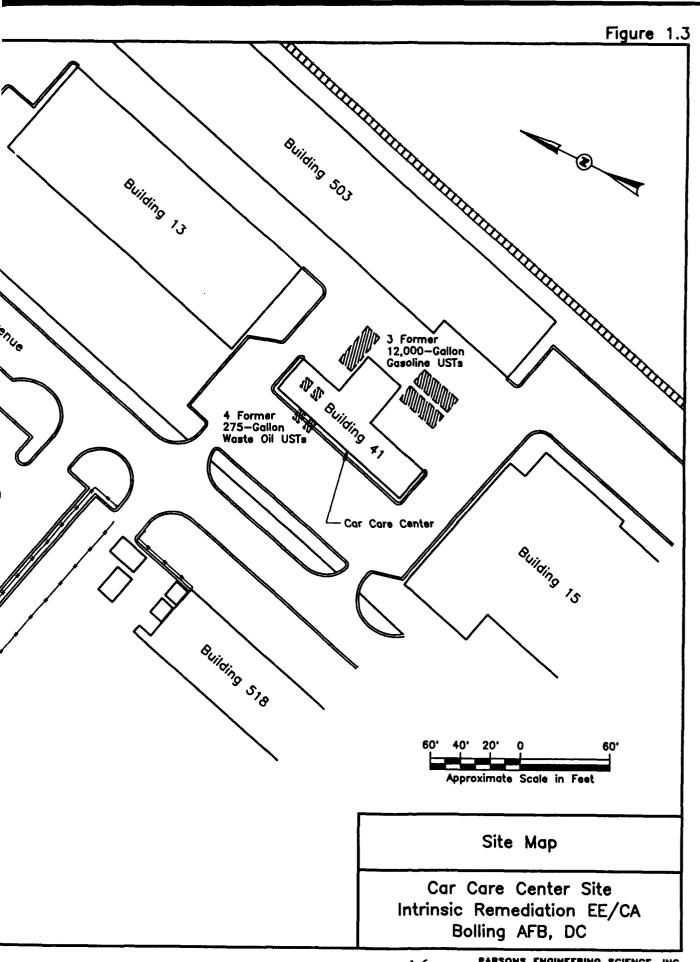

D

Ď

The locations of all the tanks formerly located onsite are shown in Figure 1.3.

Baker (1994) reported that three known product releases occurred at the site. The exact dates and volumes of the releases are unknown. Soil and groundwater contamination was observed during removal of the USTs. Several investigations have been performed onsite to determine the potential impact to site soil and groundwater. The results of these investigations are covered in several reports, including:

- ATEC Environmental Consultants (ATEC), Phase II Environmental Assessment Soil Contamination Delineation, March 1990;
- ATEC, Contaminant Assessment Report, June 1990;
- Baker Environmental, Inc. (Baker), Final Project Plans Remedial Investigations/Feasibility Study, December 1993; and
- Baker, Draft Remedial Investigation Report, May 1994.

The site-specific data presented in Sections 3, 4, and 5 are based on a review of these documents and on data collected by Parsons ES during the August 1994 and June 1996 field investigations.

1.2.2 Current Remedial Activities

Past abatement measures at the site included hand-bailing/hand-skimming of LNAPL from site monitoring wells. During March 1990, monitoring wells MW-3, MW-4, and MW-6 intermittently contained free product. Since that time, these wells have been bailed on a weekly basis to remove free product. Bailing activities were discontinued during May 1994, because the volumes of recovered product was minimal. Bolling AFB was not able to provide a summary of the actual product volumes recovered from the wells. However, this volume is expected to be relatively small due to the minimal LNAPL thicknesses observed by Parsons ES during August 1994.

In October 1996, an internal combustion engine/soil vapor extraction (ICE/SVE) system was installed at the former Car Care Center. Using a V2 ICE unit, the ICE/SVE system ran from October 16 until October 20. During this time period the ICE/SVE unit removed 144 pounds of total volatile hydrocarbons (TVH) from the site's underlying soils. On October 20, the ICE/SVE system was shut down, because of extremely high TVH concentrations in the effluent. A larger ICE unit, a V4 model, is scheduled to replace the V2 ICE unit during the week on November 4, 1996. The startup and optimization of the model V4 ICE unit at the former Car Care Center is anticipated during the week of November 11, 1996.

SECTION 2

SITE CHARACTERIZATION ACTIVITIES

This section presents the methods used by Parsons ES to collect the site-specific data at Bolling AFB, DC for the intrinsic remediation demonstration during August 1994 and June 1996. Prior investigations (Baker, 1994; ATEC, 1990) have approximately defined the dissolved and adsorbed contaminant plumes. As a first task, Parsons ES reviewed water level and chemical concentration data (Baker, 1994) from existing site wells to identify potential CPT, LIF, and monitoring point locations. Parsons ES marked these locations on a map for use by Bolling AFB to obtain the necessary utility clearances.

The August 1994 site characterization proceeded in four phases. Parsons ES and USACE utilized several investigative techniques to perform the intrinsic remediation demonstration. Phase I consisted of characterizing the site lithology and free product plume. These activities were performed concurrently with the USACE's CPT and LIF probe. Phase II consisted of soil boring and sampling using the USACE's Hoggen Toggler® soil sampler. Phase III included the installation of temporary and permanent groundwater monitoring points. The monitoring points consisted of 0.5-inch-diameter screens and casings, as discussed in subsequent sections of this report. The USACE surveyed these sampling locations during Phase III. Phase IV consisted of groundwater sampling from previously existing wells and the newly installed monitoring points.

For the purposes of this report, the term "drilling" was used generally to represent CPT/LIF testing and monitoring point installations using direct push technologies. To minimize confusion among CPT/LIF test points, soil sample locations, and monitoring point installations, Parsons ES utilized a single prefix (CPT) for all tests at a single location. The field log books and laboratory reports utilize additional prefixes to distinguish between sample types. Construction details of existing monitoring wells, USACE installed monitoring points, CPT/LIF tests, and soil sample locations are presented in Table 2.1. Test locations are shown in Figure 2.1. Data collected under this program were used to aid with interpretation of the physical setting (Section 3), contaminant distribution (Section 4), and to develop the conceptual site model (Section 5).

Parsons ES collected the following physical, chemical, and hydrogeologic data during the field work phase of the EE/CA:

- Detailed analysis of subsurface media;
- Estimation of extent and thickness of LNAPL in monitoring wells;

- Depth from measurement datum to the water table or potentiometric surface in monitoring wells and monitoring points;
- Location of potential groundwater recharge and discharge areas;
- BTEX, trimethylbenzenes (TMBs), and total volatile hydrocarbon (TVH) concentrations in soil;
- Total organic carbon (TOC) concentrations in select soil samples;
- Chemical analysis of free product to determine the mass fraction of BTEX;
- Dissolved oxygen (DO), nitrate, ferrous iron, sulfate, methane, and TOC concentrations in groundwater;
- Temperature, specific conductance, reduction/oxidation (redox) potential, total alkalinity, and pH of groundwater; and
- BTEX, TMBs, and TVH concentrations in groundwater.

Section 2.1 describes the procedures used to determine site lithology, delineate free product, and sample soil. Section 2.2 discusses the procedures for installing monitoring points, and developing monitoring wells. Section 2.3 presents the procedures for groundwater sampling.

2.1 CONE PENETROMETRY, LASER-INDUCED FLUOROMETRY, AND SOIL SAMPLING ACTIVITIES

CPT-related activities took place between 1 August 1994 and 12 August 1994. CPT, LIF, and soil sampling were accomplished using the procedures described in the following sections. Parsons ES and the USACE staff performed lithologic logging with CPT and LNAPL delineation with LIF during Phase I of the field activities. These tests were performed concurrently during the same push with the USACE's cone penetrometer truck, providing an expedient and effective means of investigating the site.

2.1.1 Pre-Drilling Activities

Parsons ES obtained all necessary digging, drilling, and groundwater monitoring well installation permits prior to mobilization. In addition, all utility lines were located and proposed drilling locations were cleared prior to any drilling activities. The USACE staff utilized an onsite potable water supply for drilling, equipment cleaning, and grouting. The Bolling AFB point of contact verified this source prior to use.

2.1.2 Cone Penetrometry Procedures

Eighteen CPT tests (Table 2.1) were performed at the Car Care Center Site (CPT-1 through CPT-18). CPT lithologic information and boring logs from previous investigations were utilized to delineate subsurface geological conditions. Appendix A contains CPT lithologic logs. Parsons ES developed soil descriptions and lithologic cross-sections to compare stratigraphy below the Car Care Center site. This

stratigraphic information is discussed in Section 3. Periodic soil samples were collected in Phase II field activities to manually compare CPT computed readings to actual soil samples, which validated the CPT data. Observed soil types corresponded very well to the CPT test data.

The intrinsic remediation study utilized a cone penetrometer truck to determine the site lithology, measure LIF response, collect soil samples, and install groundwater monitoring points at the site. The truck's weight provides the necessary reaction mass to force an instrumented probe into the ground. The penetrometer equipment is mounted on a 3-axle Kenworth chassis that provides an overall push capability of 43,000 pounds. A pair of large hydraulic cylinders bolted to the truck frame provides the penetration force.

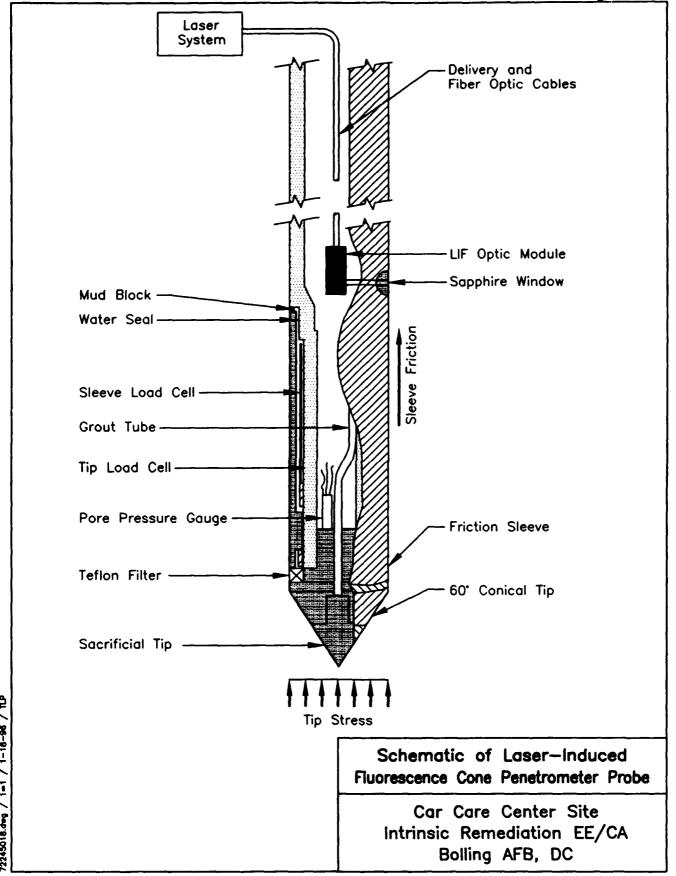

The penetrometer probe is of standard dimensions, having a 1.405-inch outside diameter (OD), 60-degree conical tip, and a 1.405-inch OD by 5.27-inch-long friction sleeve (Figure 2.2). Inside the probe, two load cells independently measure the vertical resistance against the conical tip and the side friction along the sleeve. Each load cell inside the probe is a cylinder of uniform cross section that contains four strain gauges in a full-bridge circuit. Forces are sensed by the load cells, and the data are transmitted from the probe assembly via a cable running through the push tubes. The analog data are digitized, recorded, and plotted by computer in the penetrometry truck. The penetrometer is usually advanced into the soil at a constant rate of 48 inches per minute, although this rate must sometimes be reduced (e.g., when hard layers are encountered). The magnitude of the penetration force is a function of compressibility and, most importantly, permeability.

2.1.3 Laser-Induced Fluorometry

Laser-induced fluorometry was utilized in Phase I to delineate areas of free product and excessive soil hydrocarbon concentrations. Nineteen LIF tests were performed at the Car Care Center Site (CPT-1 through CPT-18, and CPT-23). Parsons ES delineated the potential hydrocarbon source using the LIF data in combination with soil analyses. This information is summarized in Section 4. Direct printouts of the LIF logs are provided in Appendix A.

The USACE's LIF system utilized a nitrogen-based laser optics fluorometer tool, which scans for fluorescent compounds as it is pushed though the soil. The known propensity of aromatic or chlorinated hydrocarbons to fluoresce under ultraviolet wavelengths has allowed the use of LIF technology in conjunction with CPT technology to detect gross hydrocarbon contamination and soil characteristics, simultaneously. The LIF/CPT system has a sapphire window in the side of the CPT probe, which allows a laser to scan the soil for fluorescent compounds as the LIF/CPT penetrometer rod pushes through soil (Figure 2.2). Assuming that aromatic hydrocarbons are simultaneously solvenated with other fuel-hydrocarbon constituents, the magnitude of aromatic fluorescence is indicative of hydrocarbon contamination in a soil matrix. The push tubes act as a conduit for the fiber optic cable and a 6-pair electrical conductor. This wiring connects the laser spectrometer and CPT data acquisition systems to the CPT probe.

The basic laser system components of the CPT/LIF instrumentation are a Nd:YAG[®] pump laser, two separate and independent rhodomine dye lasers, frequency-doubling crystals which convert the visible-dye laser output to ultraviolet, a fiber optic probe, a monochromator for wavelength resolution of the return fluorescence, a photomultiplier tube to convert photons into an electrical signal, a digital oscilloscope for waveform capture, and a control computer. The cone penetrometer's fiber optic probe consists of a delivery and collection fiber, a protective sheath, a fiber optic mount within the cone, and a sapphire window (Figure 2.2). The uphole portion of the system is adaptable to either groundwater monitoring fiber optic probes or an optical cone penetrometer probe. Optimal wavelengths to be used during a continuous CPT push are determined during each push. The computer selects the wavelength with the strongest fluorescence signal to correlate contamination. Past experience suggested that a wavelength of less than 275 nanometers (nm) may be appropriate for detecting the fluorescence of fuel hydrocarbons.

2.1.4 Soil Sampling Procedures

Parsons ES collected soil samples from the CPT rig during Phase II of the field activities. Soil sampling served to fulfill four purposes:

- · Validate the lithological data collected during CPT tests,
- · Determine actual hydrocarbon concentrations in soils,
- Correlate the LIF laser direct readings to actual laboratory results (Figures 4.2a and 4.2b), and
- · Determine background soil geochemistry.

Parsons ES chose six CPT locations (CPT-03, CPT-07, CPT-09, CPT-11, CPT-14, and CPT-24) from which to collect soil samples (Table 2.1). These samples, in combination with the LIF data, provide horizontal and vertical delineation of hydrocarbon contamination in site soils. Parsons ES collected several soil samples from each test location to provide a vertical profile. Overall, 17 soil samples were collected, including duplicates and quality assurance/quality control (QA/QC) samples. The field logs and analytical reports reference these soil samples with a soil boring (SB) prefix followed by a number. This number refers to the CPT location indicated on all EE/CA report figures. To minimize confusion within tables and figures, the CPT prefix is utilized instead of the SB prefix.

Soil sampling was accomplished during this investigation using a Hoggen Toggler stainless steel soil sampler. The dimensions of the Hoggen Toggler spoon were approximately 1 inch (diameter) by 8 inches (long). The sampler is coupled to the penetrometer rod and pushed into the soil. While the Hoggen Toggler cone is in position, soil is prevented from entering the sampling tube until the desired depth is achieved. To operate the unit, the sampling tube is pushed to the required depth and then raised a few inches. The driller unlocks the cone from inside the truck, allowing the cone to automatically retract into the sampler barrel during sample collection. The USACE operator pulled the sampling apparatus from the ground as quickly as possible. The Hoggen Toggler sampling apparatus allowed collection of a 8-inch-long

continuous sample. Recovery efficiencies for samples in saturated soils were occasionally reduced because of spillage of the soil from the device after extraction. To mitigate this problem, soil samples were compressed in situ with the penetrometer and Hoggen Toggler assembly to expel the pore water before extraction. Compressed soil samples were then extracted and measured to give a description of the soil stratigraphy accurate for the length of soil core taken.

Soil samples were obtained from each location at a discrete depth. This depth typically corresponded to the interval with the highest LIF reading. The soil samples were removed from the sampler and placed in clean glass jars for laboratory analysis. During previous natural attenuation projects, a portion of the soil sample was placed in a clean glass jar for photoionization detector (PID) headspace measurements. However, the small volume of the Hoggen Toggler® sampling device did not allow for enough soil recovery to permit split PID analyses within one discrete sample tube. Because LIF peak readings were generally observed in thin lenses within the soil profile, sample length was minimized in order to correlate LIF readings to the analytical results. Since the PID results only provide a qualitative measure of volatile organic compounds (VOC), omission of these screenings does not effect the overall intent of the project.

The Parsons ES field hydrogeologist observed CPT and LIF testing, soil sampling, and monitoring point installation activities. The field hydrogeologist maintained descriptive notes of subsurface materials recovered. Observed soil classification types compared very favorably to the soil classifications determined by the CPT tests.

2.1.5 Equipment Decontamination Procedures

Prior to arriving onsite, and between each test location, CPT push rods were cleaned with an automatic steam-cleaning system (rod cleaner) as the rods were withdrawn from the ground. A vacuum system located beneath the CPT truck was used to recover cleaning water. Use of this system resulted in nearly 100-percent recovery of steam-cleaning rinseate from the rod cleaner. Rinseate was generated only as the rods moved past the cleaner, thereby minimizing liquid waste generation. Only potable water was used for decontamination. Rinseate was collected in 55-gallon drums provided by USACE. Filled 55-gallon drums were then staged in an area designated by the Bolling AFB point of contact. Bolling AFB arranged for disposal of the water through a local waste disposal company.

The soil samplers were disassembled upon sample collection and manually cleaned with a high-pressure steam/hot water wash. Contaminated soils (i.e., cuttings) were not generated during any field activities. Fuel, lubricants, and other similar substances were handled in a manner consistent with accepted safety procedures and standard operating practices. Well completion materials were not stored near or in areas that could be affected by these substances.

2.2 MONITORING POINT INSTALLATION AND MONITORING WELL DEVELOPMENT

Monitoring wells MW-1 through MW-10, installed during previous investigations, were constructed using standard hollow-stem auger (HSA) drilling techniques.

Standard split-spoon sampling was performed during well construction. Parsons ES reviewed boring logs for selected monitoring wells (Baker, 1994) to determine potential monitoring point screen interval locations prior to drilling. Upon completion of the CPT/LIF investigation, the USACE installed 11 multi-depth groundwater sampling points using the CPT rig. As a result, 22 additional sampling points were available to Parsons ES for groundwater sampling. Groundwater samples were collected from 10 monitoring wells and 18 monitoring points. All monitoring wells and monitoring points were utilized to determine groundwater elevation.

2.2.1 Well Locations and Completion Intervals

Ten multi-depth (nested) monitoring points were installed to help characterize the shallow groundwater flow system at the Car Care Center Site. These monitoring point locations are identified as CPT-02, CPT-08 through CPT-11, CPT-16, and CPT-19 through CPT-22. Monitoring points were not installed at location CPT-18 due to lack of available casing material at the time of construction. A Geoprobe was used at CPT-18 to collect representative water samples from depths similar to the other monitoring point screened intervals. Because CPT-18 was temporary and not cased, water level information was not obtained from this location. Table 2.1 presents well completion details for all previously existing wells and monitoring points located on the site. These locations are shown in Figure 2.1. The chosen monitoring point locations were selected to provide the hydrogeologic data necessary to adequately characterize the site.

Upon completion of Phase III activities, the USACE surveyed the top of casing horizontal and vertical locations for existing wells and newly installed monitoring points. These measurements were recorded relative to the Bolling AFB coordinate system. Survey data are summarized in Table 2.1

2.2.2 Groundwater Monitoring Point Installation Procedures

This section describes the procedures and equipment used for installation of new groundwater monitoring points with the CPT apparatus.

2.2.2.1 Monitoring Point Installation

Groundwater monitoring points were installed at 11 locations under this program. Detailed monitoring point installation procedures are described in the following paragraphs. At all locations, two separate points (each screened at different depths) were installed. At each location, the point with the shallowest screened interval was designated with the suffix "S", while the deep point was designated with the suffix "D" (e.g., CPT-02S or CPT-02D). Monitoring point completion diagrams are included in Appendix A.

2.2.2.1.1 Monitoring Point Materials Decontamination

Monitoring point construction materials were inspected by the field hydrogeologist and determined to be clean and acceptable prior to use. All monitoring point construction materials were factory sealed. Materials were inspected for possible

external contamination before use. Materials that could not be cleaned to the satisfaction of the field hydrogeologist were not used.

2.2.2.1.2 Monitoring Point Screen and Casing

The Parsons ES field hydrogeologist considered the LIF data and hydraulic characteristics of the stratum to select the screened interval for each monitoring point. During set-up at each new monitoring point location, the USACE first cored through any existing concrete to allow access to the ground surface. A steel conical tip was inserted onto a 1-meter section of screen. Then, the screen and tip was hydraulically forced into the ground to the required depth. Installation of a discrete sand pack was not possible. Construction details were noted on a Monitoring Point Installation Record form (Appendix A) and are summarized in Table 2.1. Monitoring point screens were constructed of flush-threaded, Schedule 40 polyvinyl chloride (PVC) with a 0.5-inch inside diameter (ID). The screens were factory slotted with 0.010-inch openings. Each well had a 3.28-foot screen length.

Casing with flush-mounted threads was added in 3.28-foot increments as the screen was pushed into the ground. Monitoring point casing was constructed of Schedule 40 PVC with an 0.5-inch ID. All monitoring point casing sections were flush-threaded; glued joints were not used. Upon monitoring point completion to the proper termination depth, the monitoring point casing was cut to approximately 4 inches above land surface. The field hydrogeologist verified and recorded the hole depth and the lengths of all casing sections. All lengths and depths were measured to the nearest 0.1 foot. The casing was fitted with a plastic cap constructed of the same type of material as the casing. The cap was vented to maintain ambient atmospheric pressure within the well casing. Barriers were then installed at each point until the point was either finished with a protective flush-mounted cover or permanently abandoned. This information became part of the permanent field record for the site.

2.2.2.1.3 Flush-Mount Protective Cover

Monitoring points CPT-19 through CPT-22 were permanently constructed to serve as POC wells. These were constructed inside 6-inch-diameter manways with flush-mounted steel covers. Upon sample collection, the remaining monitoring points (CPT-2, CPT-8, CPT-9, CPT-10, CPT-11, CPT-16, and CPT-18) were abandoned and grouted to the surface. Each permanent monitoring point was completed with an at-grade protective steel cover. The at-grade covers were cemented in place using a concrete pad of approximately 1-foot by 1-foot dimensions. All permanent monitoring points were completed with concrete pads that slope gently away from the protective casing to facilitate runoff during precipitation events.

2.2.2.2 Monitoring Point Development

Prior to sampling, newly installed monitoring points were developed with a peristaltic pump. Monitoring point development removes sediment from inside the monitoring point casing and flushes fines from the formation adjacent to the monitoring point screen. In points with a PVC casing, the pump's suction tubing was regularly lowered to the bottom of the well so that fines were agitated and removed from the well with the development water. Development was continued until turbidity was

minimized and the pH, temperature, specific conductivity, DO concentration, and redox potential of the groundwater had stabilized. All well development waters were collected in 55-gallon drums and transported to the Bolling AFB designated drum storage area.

2.2.2.3 Water Level Measurements

Water levels were measured at each monitoring point prior to purging and sampling. Measurements were made using an electric water level probe capable of recording to the nearest 0.01 foot. Free product thickness could not be determined within the 0.5-inch-diameter monitoring points due to the width of the oil/water interface probe. However, the field geologist noted the presence of an oily phase during monitoring point development. LNAPL thickness was measured in all monitoring wells. During the last day on the site, the water levels were measured in all site monitoring wells and monitoring points to obtain a snapshot of the potentiometric surface at the site. This information was utilized to develop the potentiometric surface map for Bioplume II model calibration.

2.2.2.4 Well Location and Datum Survey

The locations and elevations of the new monitoring points were surveyed by USACE personnel soon after well completion. The horizontal locations were measured relative to established Bolling AFB coordinates. Horizontal coordinates were measured to the nearest 1 foot. Vertical location of the adjacent ground surface was measured relative to the existing monitoring wells that had known northing, easting, and top of casing elevation data. Survey results are presented in Table 2.1.

2.3 GROUNDWATER SAMPLING

This section describes the procedures used for collecting groundwater quality samples during the August 1994 and June 1996 sampling events. Parsons ES utilized the following sampling procedures in order to maintain a high degree of QC during sampling events. Sampling of monitoring wells and points is described in Section 2.3.3.1. Sample analysis was performed by Evergreen Analytical, Inc., Wheatridge, Colorado (Evergreen Analytical).

Activities that occurred during groundwater sampling are summarized below:

- Assembly and preparation of equipment and supplies;
- Inspection of the well integrity (for monitoring well sampling), including
 - Protective cover, cap and lock,
 - External surface seal and pad,
 - Well stick-up, cap, and datum reference, and
 - Internal surface seal;
- Groundwater sampling, including

- Water level measurements,
- Visual inspection of water,
- Well casing or monitoring point evacuation,
- Onsite measurement of physical parameters, and
- Sampling;
- Sample preservation and transport, including
 - Sample preparation.
 - Sample labeling,
 - Transport of samples to Evergreen via. overnight courier;
- · Completion of sampling records; and
- Sample disposition.

Detailed groundwater sampling and handling procedures are presented in following sections.

2.3.1 Groundwater Sampling Locations

Groundwater samples were collected from existing monitoring wells and from newly installed groundwater monitoring points.

2.3.1.1 Monitoring Well Sampling Locations

Groundwater samples were collected from 10 existing monitoring wells (MW-1 through MW-10), during the 1994 sampling event. In June 1996, groundwater samples were collected from 6 monitoring wells (MW-1 and MW-7 through MW-11). All wells were purged using a peristaltic pump with dedicated polyethylene tubing. A dedicated disposable bailer was used to collect the samples in August 1994, and in June 1996 samples were collected using a peristaltic pump and dedicated polyethylene tubing. Additional sampling procedures are discussed in Section 2.3.3. Locations of these wells are indicated on Figure 2.1.

2.3.1.2 Monitoring Point Locations

Groundwater samples were collected from 18 monitoring points across the site during the August 1994 sampling event. The deep and shallow intervals were sampled at CPT-2, CPT-8 through CPT-11, CPT-16, and CPT-18. However, only the deep samples were collected at CPT-19 through CPT-22. Adequate purge and sample volumes could not be obtained from these shallow locations. During the June 1996 sampling event, CPT-19 through CPT-22 were sampled, and once again only deep points were sampled because adequate purge and sample volumes could not be obtained from these shallow locations. Monitoring points were purged and sampled using a

peristaltic pump and dedicated tubing (where needed). Locations of groundwater monitoring points are indicated on Figure 2.1.

2.3.2 Preparation for Sampling

All equipment sed for sampling was assembled and properly cleaned and calibrated (if required) prior to arriving in the field. In addition, all record-keeping materials were gathered prior to leaving the office.

2.3.2.1 Equipment Cleaning

All portions of sampling and test equipment that contacted the samples were thoroughly cleaned before use. This equipment included the water level probe and cable, lifting line, test equipment for onsite use, and other equipment that contacted the samples or was placed downhole. The following cleaning protocol was used:

- Cleaned with potable water and phosphate-free laboratory detergent;
- · Rinsed with potable water;
- Rinsed with isopropanol;
- · Rinsed with distilled or deionized water;
- Air dried prior to use.

Any deviations from these procedures were documented in the field scientist's field notebook and on the groundwater sampling form.

2.3.2.2 Equipment Calibration

As required, field analytical equipment were calibrated according to the manufacturer's specifications prior to field use. This applied to equipment used for onsite chemical measurements of DO, redox potential, pH, specific conductivity, and temperature.

2.3.3 Sampling Procedures

Special care was taken to prevent cross-contamination of the groundwater, groundwater samples, and sampling equipment. Water level probes and cable used to determine static water levels and well total depths were thoroughly cleaned before and after field use and between uses at different sampling locations according to the procedures presented in Section 2.3.2.1. Generally, sample probes were utilized within a flow-through container which was installed downstream of the peristaltic pump. Samples were either collected using dedicated polyethylene tubing and a peristaltic pump, or from a dedicated bailer. In addition, the sampler donned a new pair of disposable nitrile gloves at each sampling station.

2.3.3.1 Groundwater Monitoring Well and Monitoring Point Sampling

2.3.3.1.1 Preparation of Location

The area around each monitoring well/point was cleared of foreign materials, such as brush, rocks, and debris prior to sampling. This prevented sampling equipment from inadvertently contacting debris around the monitoring well/point.

2.3.3.1.2 Water Level and Total Depth Measurements

Prior to removing any water from the monitoring well or monitoring point, the static water level was measured. An electric water level probe was used to measure the depth to groundwater to the nearest 0.01 foot below the datum. After measuring the static water level, the field scientist slowly lowered the water level probe to the bottom of the monitoring point. The total depth was measured to the nearest 0.01 foot.

2.3.3.1.3 Monitoring Well/Point Purging

The volume of water to be purged from the monitoring well/point was calculated. The field scientist purged at least three times the calculated volume from the well/point using a peristaltic pump and dedicated tubing. Parsons ES maintained a low flowrate from the peristaltic pump during purging and sampling all monitoring wells/points. This minimizes evaporation (boiling) of the water in the suction line due to decreased pressures, minimizes excess mixing and aeration in the sample container, and ensures that the well does not become dry (entrain air in the suction line). All purge water was placed in 55-gallon drums and disposed of by Bolling AFB. The emptied drums remained with Bolling AFB for reuse.

2.3.3.1.4 Sample Extraction

The following sample extraction procedures are designed to minimize sampled disturbance and subsequent volatilization of VOCs. Generally, the VOC concentration data collected under the intrinsic remediation program are higher than data gathered previously at the site. However, concentrations once again begin to decrease when using the same sampling techniques during LTM. This implies that fewer VOCs are lost from the samples while following the protocols developed under the intrinsic remediation program.

Dedicated high-density polyethylene (HDPE) tubing and a peristaltic pump were used to extract groundwater samples from the monitoring points. The suction end of the tubing was slowly lowered down the casing to prevent splashing. A dedicated disposable bailer was used to collect the groundwater sample from monitoring wells. The samples were transferred directly into the appropriate sample container(s), with water carefully poured down the inner walls of the sample bottle to minimize aeration of the sample. Sample containers were filled completely (zero headspace) to minimize volatilization.

Excess water collected during sampling was placed into the 55-gallon drums used for monitoring well/point purge waters. Upon project completion, Parsons ES transported the drums to the Bolling AFB designated drum storage location.

2.3.4 Onsite Chemical Parameter Measurement

Most chemical parameters of groundwater can change significantly within a short time following sample acquisition. As a result, these parameters were measured in the field immediately after collection. The following procedure was utilized during groundwater sampling for all direct reading instruments (e.g., DO, redox, pH, temperature, and electric conductivity). An Erlenmeyer flask was installed downstream from the peristaltic pump to form a flow-through chamber for the sampling probes. As a result, a continuous measurement from the direct reading instruments was possible. The extracted groundwater flowed over the probes while immersed in the Erlenmeyer flask. This effectively produces a flow-through cell that minimizes aeration of the sample. Pumping continued until the readings stabilized. The stabilized reading was recorded.

2.3.4.1 Dissolved Oxygen Measurements

DO measurements were taken using an Orion® model 840 (or similar DO measurement instrument) using the above described procedures. DO concentrations were determined while the probe was immersed in an Erlenmeyer flask. This effectively minimized aeration of the sample. DO concentrations were recorded after the readings stabilized. In all cases, the lowest DO concentration was recorded.

2.3.4.2 Reduction/Oxidation Potential Measurements

Redox potential measurements were taken using an Orion[®] model 290A redox potential meter. Redox potential measurements were recorded after the readings stabilized and generally represent the lowest redox potential observed.

2.3.4.3 Temperature, pH, and Electric Conductance

Temperature and pH were determined with an Orion® model 290A meter with an ion select probe. These parameters were recorded after the readings stabilized and generally represent the average reading after stabilization. Electrical conductance was not measured during either sampling event.

2.3.5 Sample Handling

2.3.5.1 Sample Preservation

Evergreen Analytical added any necessary chemical preservatives to sample containers prior to sampling.

2.3.5.2 Sample Container and Labels

Sample containers and appropriate container lids were provided by Evergreen Analytical. The sample containers were filled as described in Section 2.3.3.1.4, and the container lids were tightly closed. The sample label was firmly attached to the container side, and the following information was legibly and indelibly written on the label:

- Facility name;
- Sample identification;
- Sample type (i.e., groundwater);
- · Sampling date;
- · Sampling time;
- Preservatives added; and,
- Sample collector's initials.

2.3.5.3 Sample Shipment

The samples were sealed, labeled, and placed in an iced cooler. Then, coolers were packaged for transport to Evergreen Analytical via Federal Express[®] priority delivery. The following packaging and labeling procedures were followed:

- Sample was packaged to prevent leakage or vaporization from its container;
- · Shipping container was labeled with
 - Sample collector's name, address, and telephone number;
 - Laboratory's name, address, and telephone number;
 - Description of sample;
 - Quantity of sample; and
 - Date of shipment.

Generally, the packaged samples were hand-delivered directly to the Federal Express[®] facility at the end of each day.

2.4 AQUIFER TESTING

Prior to initiation of the field activities, Parsons ES reviewed the slug test methodologies performed by Baker (1994) at the Car Care Center Site. Baker performed slug tests in monitoring wells MW-7, MW-8, MW-9, and MW-10. These methodologies appeared consistent with the protocols established for the Intrinsic Remediation program (Wiedemeier et al., 1994). Hydraulic conductivity (K) was calculated from established analytical methods (Bouwer and Rice, 1976; Bouwer, 1989). Reported K values were reasonable for the aquifer material at the site. K values also were consistent among the four wells tested. As a result, Parsons ES did not perform additional aquifer testing at the site.

SECTION 3

PHYSICAL CHARACTERISTICS OF THE STUDY AREA

This section incorporates data collected during investigations by ATEC (1990) and Baker (1994) with data from more recent investigations conducted by Parsons ES. The investigative techniques used by Parsons ES to determine the physical characteristics of the Car Care Center Site are discussed in Section 2.

3.1 SURFACE FEATURES

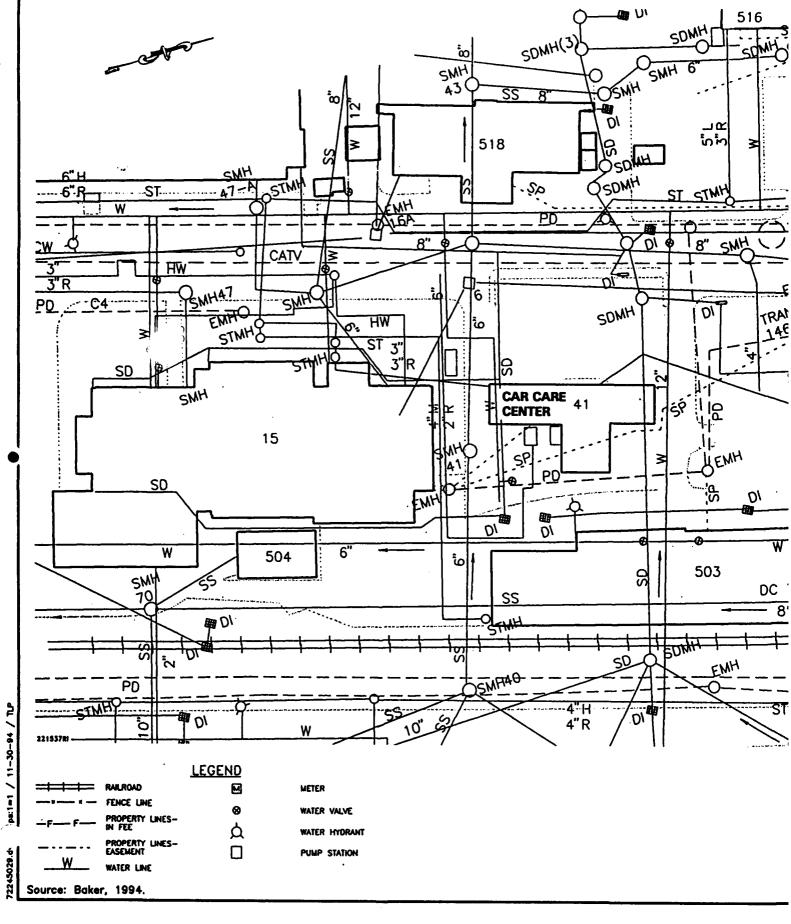

3.1.1 Topography and Surface Water Hydrology

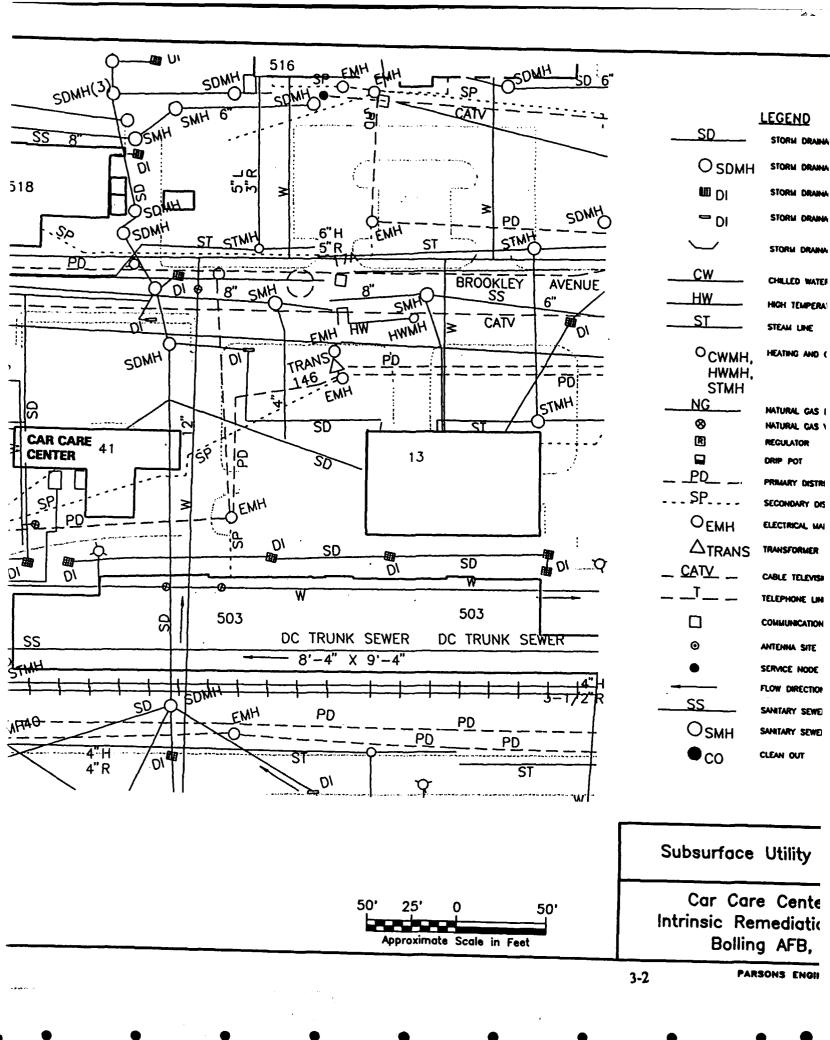

The Car Care Center Site is located in the floodplain along the eastern shore of the Potomac River, just south of the confluence of the Potomac and Anacostia River (Figure 1.1). The ground surface at the base is nearly level, with the exception of a steep rise along the eastern boundary of the base corresponding to the terraces above the Potomac River floodplain. The floodplain area within Bolling AFB has been extensively filled during development of the base for flood control. In addition, the Potomac shoreline was filled and extended during the 1930s and 1940s to provide additional space for base expansion (Baker, 1994). The Car Care Center is located at approximately 22 feet above mean sea level (msl), 20 feet above the Potomac River. Any significant elevation changes at Bolling AFB and surrounding areas are the result of erosion, filled wetlands, and/or stream channel development.

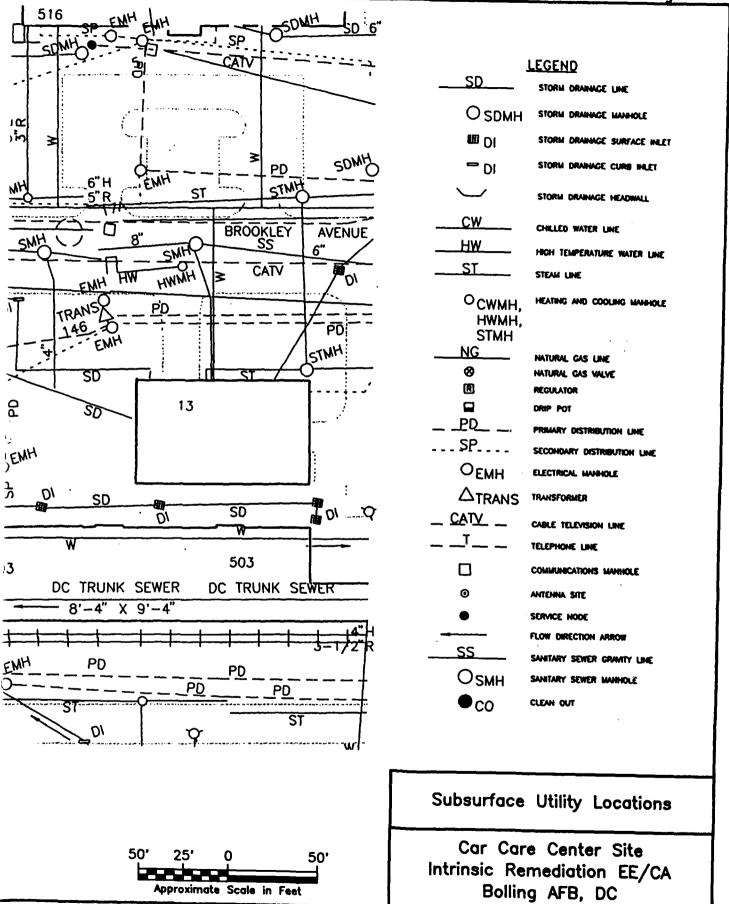

The entire Washington, DC area is drained by the Potomac River, which is fed by its local tributaries: the Anacostia River and Rock Creek in the north, and Difficult Run, Pimmit Run, Holes Run and Accotink Creek in the south. Surface water runoff at the base, which is not intercepted by the base storm water drainage system, flows westward overland toward the Potomac River. There are no naturally occurring surface water bodies in the vicinity of the Car Care Center. There are several manmade features at or near the site that may influence surface water runoff. These features are discussed in Section 3.1.2.

3.1.2 Manmade Features

Land surface cover at the Car Care Center and adjacent areas consists of grassy landscaped areas, asphalt paving, concrete overlays, buildings, and other impervious structures. The majority of the precipitation that falls on the base either infiltrates into the subsurface or is captured by the storm water drainage system. Numerous subsurface utilities, including storm sewers, are located in the vicinity of the Car Care Center. Figure 3.1 shows the subsurface utility layout in the vicinity of the Car Care Center. Subsurface utilities in the vicinity of the site probably have little influence on

groundwater flow because the water table is about 20 feet below land surface (bls), substantially deeper than typical utility trench depths. However, utility trenches may affect subsurface infiltration and flow of water and contaminants in the vadose zone.

3.2 REGIONAL GEOLOGY AND HYDROGEOLOGY

Washington, DC straddles the fall line which separates the Piedmont Physiographic Province on the northwest from the Atlantic Coastal Plain Physiographic Province on the southeast (Smith, 1976). The fall line passes from Fort Belvoir, Virginia on the south through Roosevelt Island and DC to Silver Spring, Maryland on the north. Bolling AFB is located along the inner margin of the Atlantic Coastal Plain Physiographic Province, a wide wedge-shaped belt of Cretaceous to Recent sedimentary deposits (Foster, 1950). The Coastal Plain terrain consists of well dissected to gently rolling upland areas and flat lowland areas. Surface features include hills, terraces, and well defined stream valleys with steep walls and flat floodplains.

The Atlantic Coastal Plain deposits consist of unconsolidated sediments made up of mixtures of interlayered clay, silt, sand, shell, and gravel approximately 700 to 1,000 feet thick. These sediments thicken to the southeast and dip toward the east (Darton, 1950). The Coastal Plain sediments feather onto crystalline igneous and metamorphic Piedmont rocks along the fall line in northwestern Washington DC. The Piedmont rocks dip steeply to the east. Because the Coastal Plain sediments were deposited under a wide range of subaerial and near-shore environments, the strata are not continuous over long distances (Johnston, 1978).

The area between the main portion of the Base and the uplands along the eastern porder is underlain by Pleistocene and Recent river terrace deposits of the Pamlico Formation. These deposits consist of up to 30 feet of sand, gravel, silt, and clay, and may be overlain by fill. Cretaceous sediments of the Potomac Group, consisting of silty clay interbedded with sand and gravel lenses, underlie the Quaternary deposits. Potomac Group sediments outcrop in the upland area in the extreme eastern portion of Bolling AFB. These sediments include sands and clay of the Cretaceous Patapsco Formation and the dark-gray massive Arundel Clay. The Patapsco Formation is one of the more productive aquifers in the Washington, DC area (Johnston, 1978).

A soil survey of the District of Columbia (Smith, 1976) indicates that Bolling AFB is underlain by a variety of surficial soils. These soils primarily consist of (1) Udorthents; heterogeneous earthy fill materials placed over drained areas of a floodplain, (2) Luka-Lindside-Codorus association; deep, nearly level, moderately well drained soils underlain by stratified alluvial sediment or dredge material on a floodplain, and some (3) Urban Land; developed areas where more than 80 percent of the surface is covered by asphalt, concrete, buildings, or other impervious surfaces. Because the Washington DC area has not been glaciated, uplands and hillsides are typically covered by deep residual soils.

3.3 SITE GEOLOGY AND HYDROGEOLOGY

Characterization of the vadose zone and shallow unconfined aquifer at the Car Care Center Site has been the objective of several investigations. For this study, 24 locations were investigated using CPT in conjunction with LIF to examine site

lithology and hydrocarbon contamination. During the investigations of August 1994 and June 1996, there were 10, 4-inch-diameter groundwater monitoring wells (MW-1, MW-2 and MW-3 through MW-11), and four pairs of permanent nested 0.5-inch-diameter monitoring points (CPT-19 through CPT-22, shallow and deep intervals). Seven pairs of temporary nested 0.5-inch-diameter monitoring points (CPT-2, CPT-8, CPT-9, CPT-10, CPT-11, CPT-16, and CPT-18; shallow and deep intervals) were also installed and sampled during the initial August 1994 site investigation. MW-2 was sampled during the August 1994 sampling event, was destroyed shortly there after, and replaced with MW-11 which was sampled in June 1996. Figure 3.2 shows the locations of the monitoring wells and the CPT test points. To minimize confusion among CPT test points, LIF test points, and monitoring point installations, a single prefix (CPT) was used to label all locations of CPT testing and all monitoring points installed with the cone penetrometer rig. Table 2.1 presents a summary of the actual tests performed and available well and monitoring point completion information.

3.3.1 Lithology and Stratigraphic Relationships

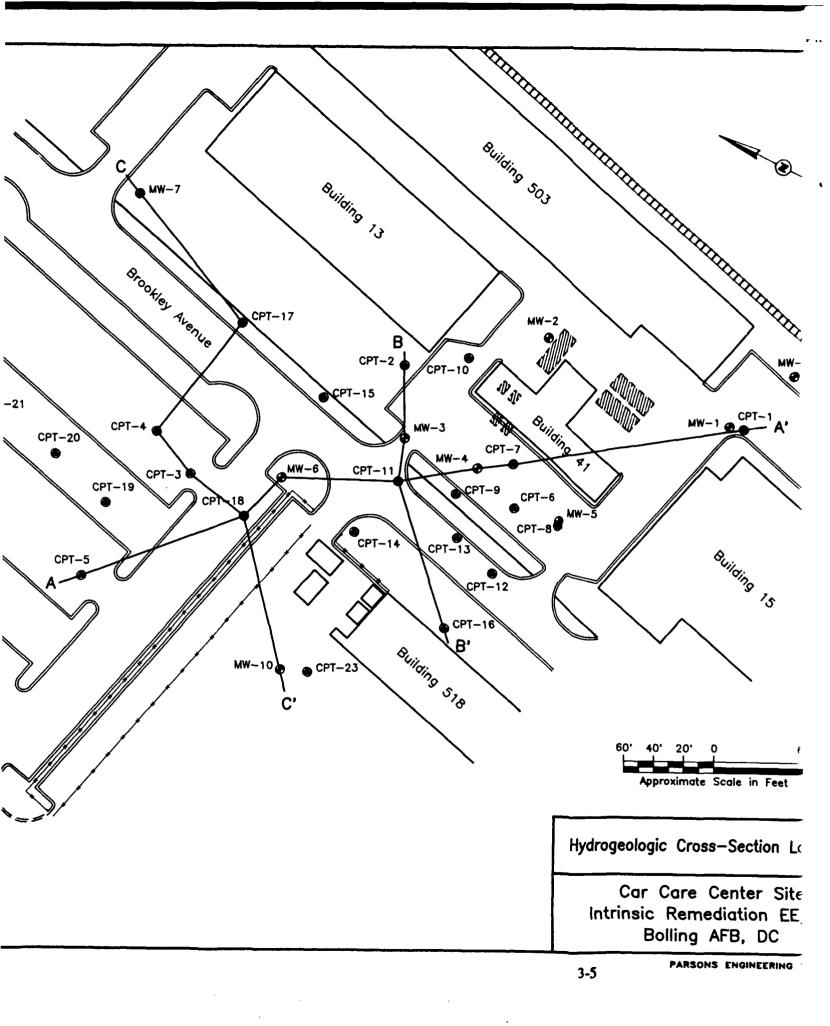

The sediments underlying the Car Care Center consist of naturally deposited interbedded alluvial sands, silts, clays, and gravel. The top 5 to 15 feet of sediment consists of a continuous bed of sand with silt, dipping and becoming thicker to the north. A localized clay lens about 1 to 2 feet thick has been observed at approximately 10 to 15 feet bls in the area along the north side of the Car Care Center. discontinuous layer of sand with minor amounts of gravel from 6 to 11 feet bls was present in some areas. Underlying these sediments is a 3- to 5-foot thick region of clay interbedded with silt. This in turn, is underlain by sand with silt and minor amounts of clay. Below about 20 feet bls, sand with gravel is present. The actual base of the surficial aquifer was not determined with certainty during this or previous investigations. Baker (1994) reported that the sandy-gravel zone may extend to 700 to 1,000 feet bls. Because these are alluvial sediments, many units are discontinuous and vary in thickness along their length. Some strata pinch out entirely within the study area. The clay layers may act to form localized small-scale perched aquifers, thereby producing relatively shallow regions of hydrocarbon contamination, as observed at CPT-12 and CPT-13 (Appendix A). Although the subsurface geology at the site is classified as mostly sand with varying amounts of silt, gravel and clay, an attempt to differentiate between more and less permeable layers was performed to clarify where perched groundwater conditions might exist at the site.

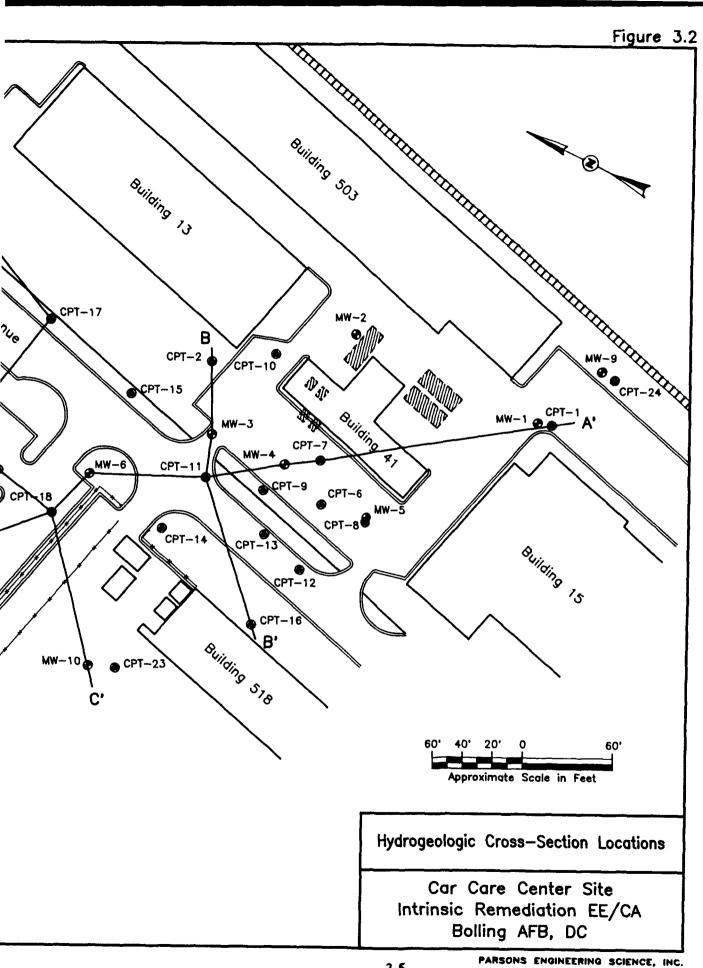

These stratigraphic relationships are illustrated by hydrogeologic sections A-A', B-B', and C-C'. Figure 3.2 shows the location of these sections. Figure 3.3 displays hydrogeologic section A-A' which is oriented approximately parallel to the direction of groundwater flow. Figures 3.4 and 3.5 display hydrogeologic sections B-B' and C-C', respectively, which are oriented approximately perpendicular to the direction of groundwater flow.

3.3.2 Groundwater Hydraulics

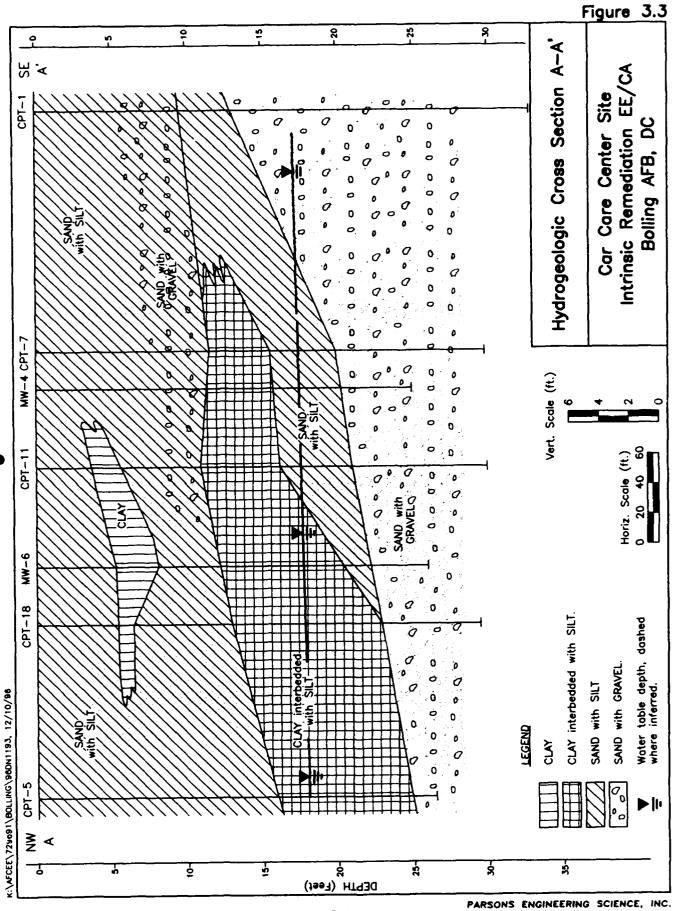

3.3.2.1 Groundwater Flow Direction and Gradient

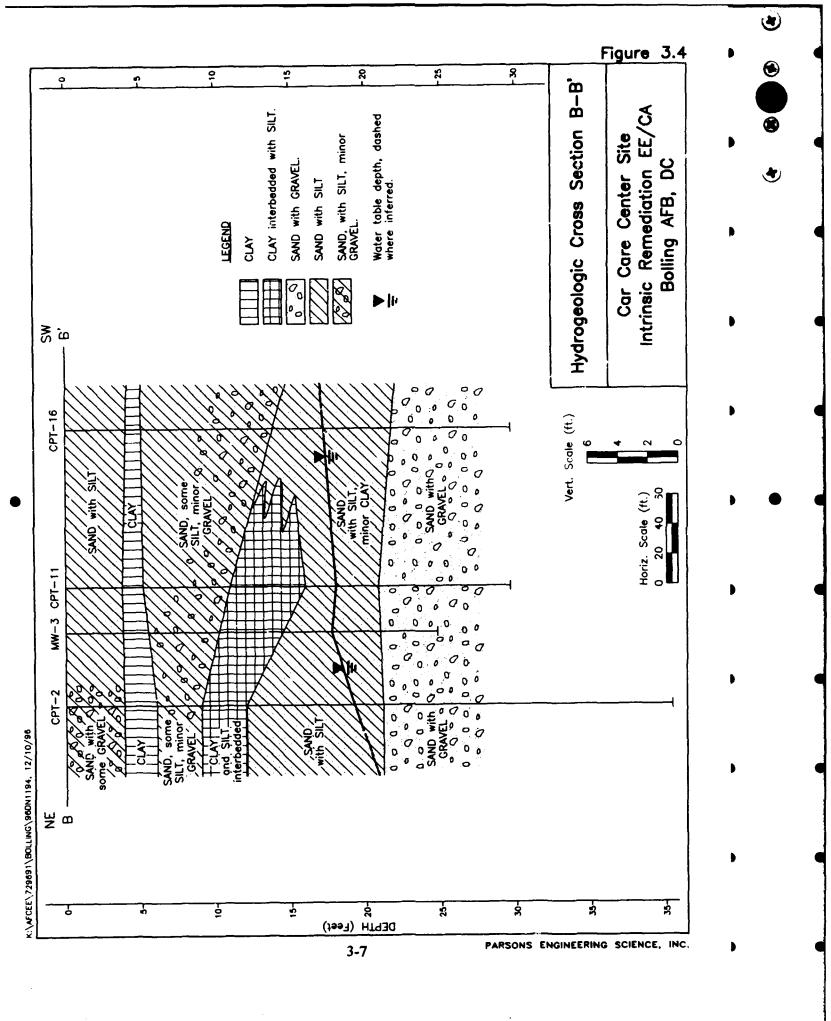

The uppermost hydrogeologic unit at Bolling AFB consists of an unconfined aquifer within the alluvium, river terrace deposits, and fill materials. Groundwater flow

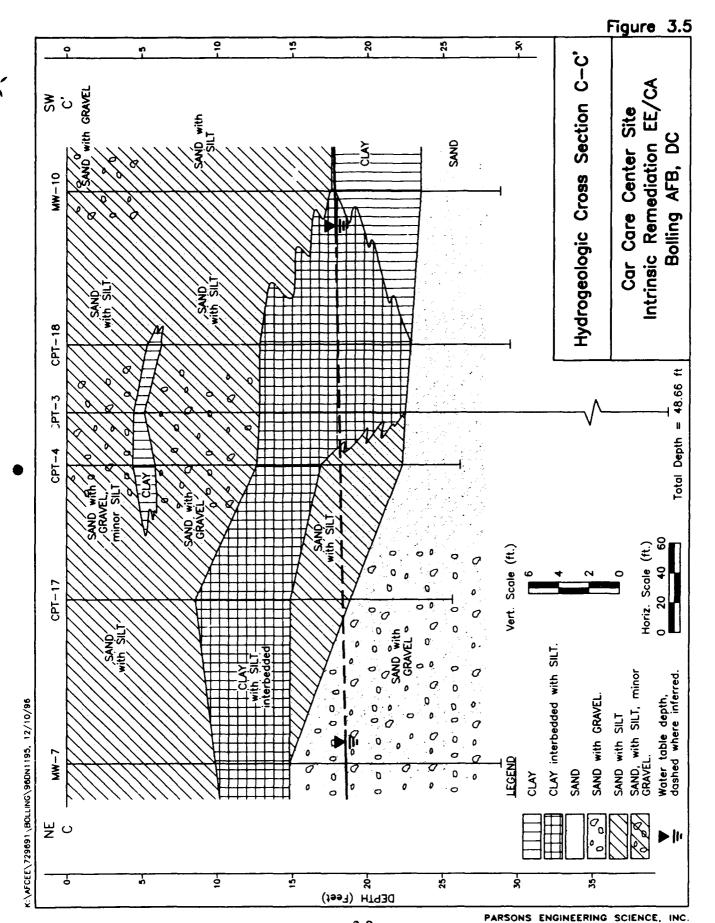

(4)

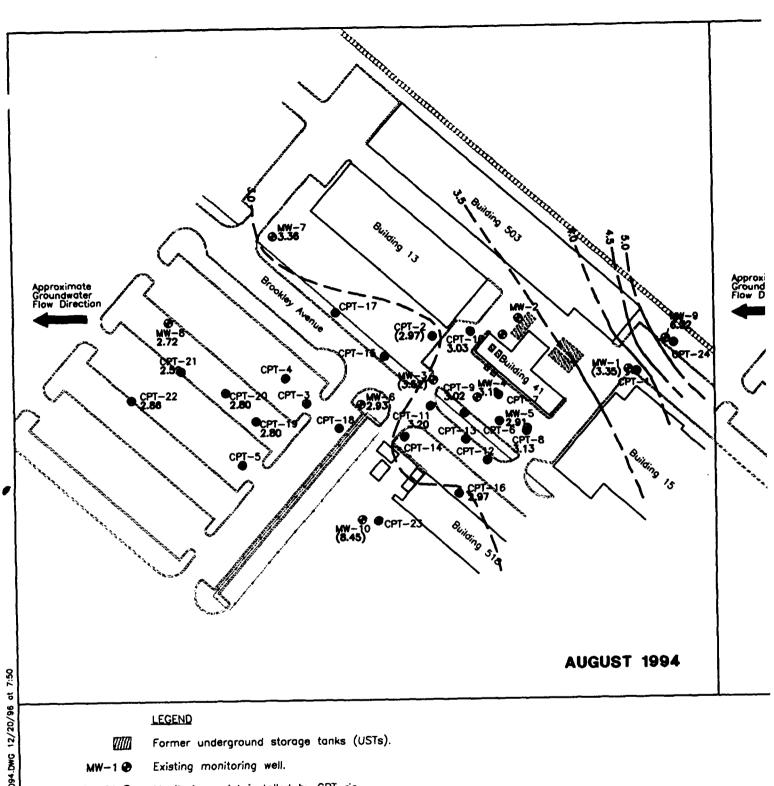

directions within the surficial unconfined aquifer are generally westerly toward the Potomac River. Groundwater at the Car Care Center Site is typically encountered at a depth of approximately 20 feet bls. However, a perched water table has also been observed at the site at depths ranging from 8 to 12 feet bls in several borings and monitoring wells.

Groundwater elevations within the shallow aguifer range from approximately 2 to 5 feet msl and approximately 9 to 10 feet msl in the perched zone near MW-10. Figure 3.6 compares two potentiometric surface maps of the unconfined aquifer at the site based on groundwater elevations measured in monitoring wells and monitoring points collected during both the August 1994 and the June 1996 sampling events (Table 3.1). Groundwater elevations observed in some wells were anomalous and were not used in construction of the potentiometric surface map. The water level in MW-10, for example, is much higher than in surrounding wells and monitoring points. In June 1996, monitoring well MW-10 and deep monitoring points CPT-19 and CPT-20 had considerably higher water levels than the surrounding wells. These anomalies at CPT-19 and CPT-20 could result from location in a landscaped area that is regularly watered, and intermittent impermeable clay layers that exist throughout the site and are present just upgradient of CPT-19 and 20. Either of these combinations or a combination of both could lead to a perched water table in the immediate vicinity of CPT-19 and CPT-20. The direction of groundwater flow (Figure 3.6) in the unconfined aquifer at the site, based on groundwater elevations in site monitoring wells and monitoring points taken during both sampling events, is to the west northwest toward the Potomac River.

The average horizontal hydraulic gradient reported by Baker (1994) was 0.0028 foot/foot. The observed gradient developed from the data collected during that investigation was higher in the upgradient area of the site and leveled out substantially in the direction of the river. A sharp rise in site topography near the upgradient portion of the site due to the Potomac floodplain terraces (see Section 3.1.1) may account for the higher observed gradient. A horizontal gradient of 0.026 foot/foot was calculated in the vicinity of MW-9, which indicates the magnitude of change in horizontal hydraulic gradient near the upgradient site boundary. A gradient of approximately 0.0014 foot/foot was measured through the center of the site between MW-4 and CPT-20 from the August 1994 site investigation. The 0.0014 foot/foot gradient value is more indicative of head potential within the primary area of plume migration because the 0.0028 foot/foot value partially includes the higher head conditions observed near the upgradient site boundary (Figure 3.6).

Vertical gradients were calculated across the site at the multidepth monitoring points. Vertical gradients ranged from 0.17 foot/foot (upward) at CPT-22 to -0.13 foot/foot (downward) at CPT-21. The average vertical hydraulic gradient was -0.0040 foot/foot (downward). Vertical gradient variances can be effected by several factors including localized infiltration zones (e.g., storm retention ditches, leaking utility piping), regional discharge areas (e.g., rivers or lakes), presence of inconsistent surface cover, and varying lithological structures. Because CPT-21 and CPT-22 are in the same general vicinity, they are likely effected similarly by local infiltration. As a result, the observed variations in vertical gradient are likely due to lithological differences which likely exist randomly across the site. Due to this circumstance, definitive conclusions cannot be drawn regarding the effects of vertical hydraulic

CPT-20 Monitoring point installed by CPT rig.

gradients on contaminant migration. Observed vertical and horizontal migration patterns of dissolved BTEX and inorganic geochemical parameters are discussed in Section 4.

3.3.2.2 Hydraulic Conductivity

As discussed in Section 2.4, Parsons ES reviewed the slug test methodologies performed by Baker (1994) at the Car Care Center Site, prior to initiation of the field activities. These methodologies appeared consistent with the protocols established for the Intrinsic Remediation program (Wiedemeier et al., 1994), and the hydraulic conductivity (K) values reported by Baker were within the acceptable range for sandy materials (Freeze and Cherry, 1979). Therefore additional slug tests were not performed and the following is a summary of the Baker (1994) results. Slug tests were conducted in monitoring wells MW-7, MW-8, MW-9, and MW-10. Reported K values ranged from 5.8 x 10⁻⁵ foot/second (foot/sec) in MW-7 to 5.8 x 10⁻⁶ foot/sec in MW-9. The average hydraulic conductivity was reported to be 2.9 x 10⁻⁵ foot/sec.

3.3.2.3 Advective Groundwater Velocity

Baker Environmental, Inc. (1994) calculated the average advective groundwater flow velocity from Darcy's Law. Using the average hydraulic conductivity of 2.9 x 10^{-5} foot/sec, the reported horizontal hydraulic gradient of 0.0028 foot/foot, and an assumed effective porosity of 0.35, Baker calculated an groundwater flow velocity of 7.3 feet/year.

As a result of groundwater sampling during the August 1994 field activities, Parsons ES determined that the contaminant plume is approximately 560 feet long (see Section 4.3.1.1). An overall plume formation time of 76 years was calculated, assuming completely conservative transport. However, the historical record indicates actual plume formation time was approximately 25 to 30 years. Based upon this brief analysis, the reported average hydraulic conductivity (2.9 x 10⁻⁵ foot/sec) may be lower than the actual overall value for the site because it does not adequately describe the overall length of the BTEX plume. Parsons ES developed a groundwater model for the site and calibrated this model to the observed site conditions. As a result, an apparent hydraulic conductivity was calculated (see Section 5.0) for use within the transport model.

3.3.3 Preferential Flow Paths

No preferential contaminant migration pathways were identified at the site. Although numerous subsurface utilities underlie the area of investigation, no effects on contaminant distribution or groundwater flow pattern were noted. Subsurface utilities at this site are not sufficiently deep to influence groundwater flow.

3.3.4 Groundwater Use

Groundwater from the surficial unconfined aquifer at Bolling AFB is not exploited for potable water supply. There were no drinking water supply wells identified on or near the base (Baker, 1994). Within a 4-mile radius of the base, no users of groundwater in the surficial aquifer were identified. Potable water supply for the base

and the surrounding area is obtained from the Blue Plains Treatment Plant located south of Bolling AFB. This plant obtains its water from the Potomac River (Freeman, 1994).

3.4 CLIMATOLOGICAL CHARACTERISTICS

The Washington, DC area has a temperate climate resulting from its latitude and its close proximity to the Atlantic Ocean. Spring and fall are characterized by a succession of warm and cold periods associated with storm activity. Summers and winters are humid, intensifying the respective heat and cold of the seasons (Flohn, 1969). The mean precipitation for the base is approximately 42 inches per year (Baker, 1994). Daily temperatures, on average, range from 27 to 86 degrees Fahrenheit (ES, 1985). Potential net infiltration of precipitation into the subsurface was calculated to be 5.6 inches annually (Baker, 1994). The prevailing wind direction during the summer months is from the south, while during the fall and winter the winds originate from the northwest.

SECTION 4

NATURE AND EXTENT OF CONTAMINATION AND SOIL AND GROUNDWATER GEOCHEMISTRY

4.1 SOURCE OF CONTAMINATION

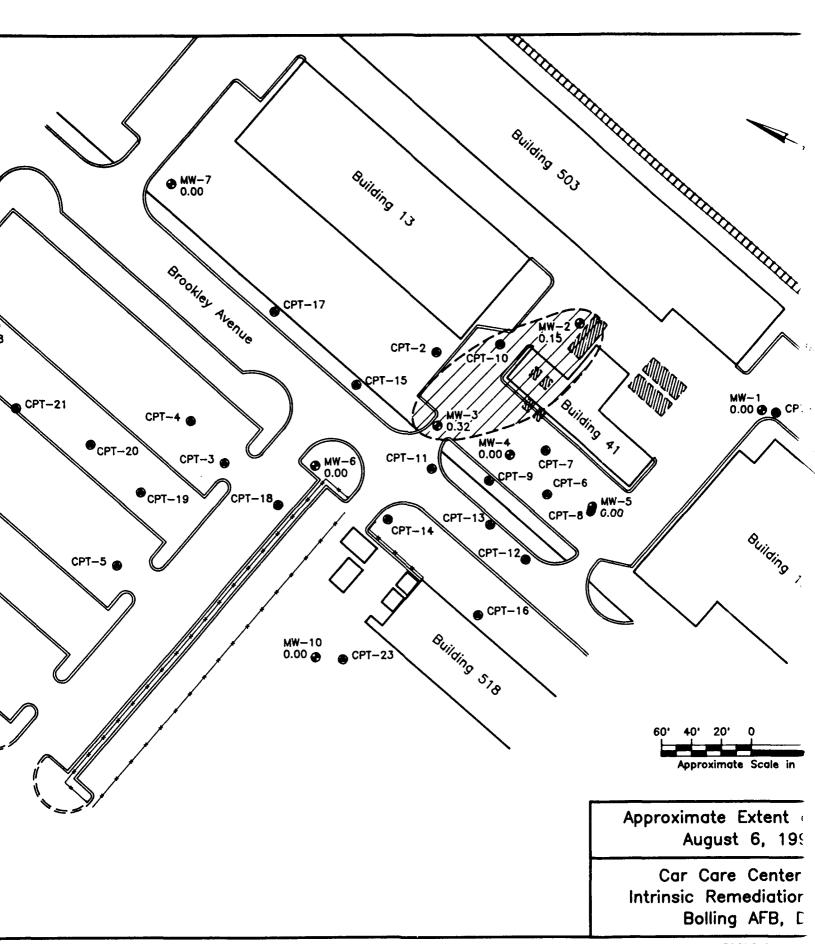

The Car Care Center facility ceased dispensing gasoline in 1982. Prior to that time, three known releases had occurred. The exact details, dates, and volumes of these releases were not available at the time this report was prepared. However, the earliest release may have occurred over 15 years ago. Data from this study suggest that the former 12,000-gallon gasoline UST, which was located near the northeastern corner of the facility, was likely a large contributor to the groundwater contaminant plume. Several highly contaminated soil samples collected from the northwest side of the Car Care Center (Building 41) indicate possible releases from the dispensers and/or fuel lines. The LIF data indicated soil contamination beneath the entire Car Care Center site and extending across Brookley Avenue.

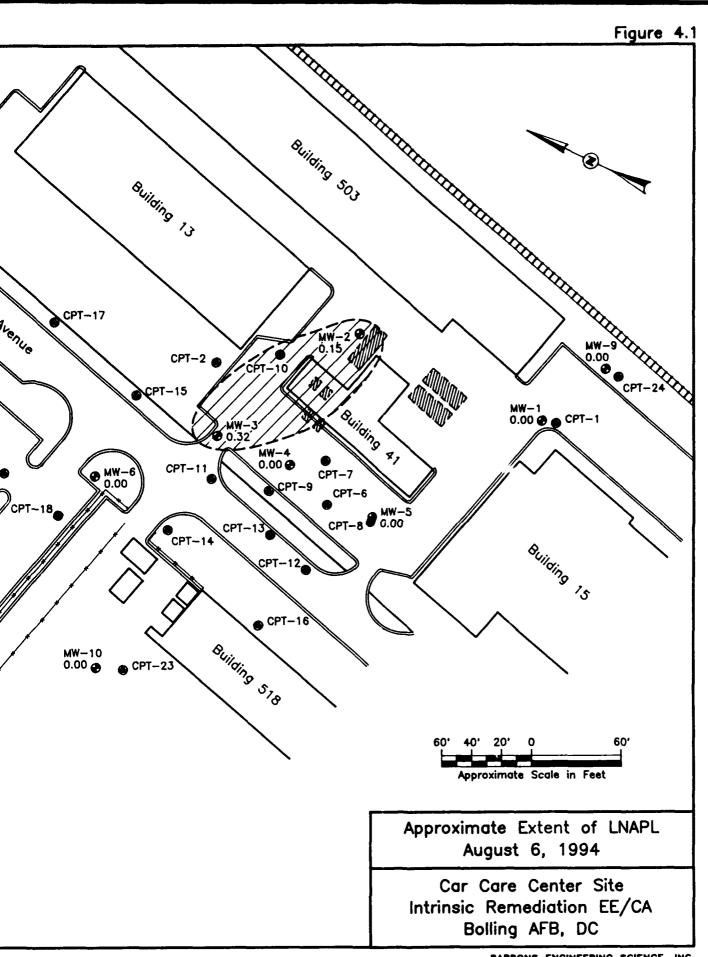

Remedial activities performed on site have included removal of the three gasoline USTs, excavation of residual soil contamination near the USTs, removal of dispensers and underground fuel piping, recovery of free product from monitoring wells, and removal of four waste oil USTs. As evident from the LIF data and analytical results from soil samples, areas of significant soil contamination still exist. These areas are likely acting as continuing hydrocarbon sources for groundwater contamination.

4.2 SOIL CHEMISTRY

4.2.1 Residual Contamination

Residual LNAPL is defined as the LNAPL that is trapped in the aquifer by cohesive and capillary forces. Therefore, residual LNAPL will not flow within the aquifer nor will it flow from the aquifer matrix into a well under the influence of gravity. Mobile LNAPL is defined as the LNAPL that is free to flow in the aquifer and that will flow from the aquifer matrix into a well under the influence of gravity. During the August 1994 sampling event, minimal mobile LNAPL thicknesses (Table 3.1) were detected in monitoring wells MW-2 and MW-3 (Figure 4.1) during the early phases of this investigation. In August 1994, a mobile LNAPL sample taken from MW-3 was submitted for composition analysis. Results suggest mobile LNAPL at the Car Care Center is weathered gasoline. BTEX composition, percent by weight, is as follows: benzene 0.3%, toluene 4.5%, ethylbenzene 1.3%, xylenes 7.7%. During the June 1996 sampling event, free product was only measured in MW-11; MW-2 and MW-3 had been removed. The following sections describe the residual LNAPL contamination found at the Car Care Center.

(4)

4.2.1.1 Soil BTEX Contamination

Residual hydrocarbon contamination resulting from vertical and lateral migration of free and dissolved hydrocarbons was found over a wide area at the Car Care Center Site during the August 1994 site investigation. Soil samples were not collected during the June 1996 sampling event. It appears that the hydrocarbons detected by LIF are primarily residual LNAPL and not mobile LNAPL, because monitoring points and monitoring wells installed at or near these locations have contained only minimal free product on an infrequent basis. Table 4.1 contains analytical results for BTEX and TVH in soils. Figures 4.2a and 4.2b show the extent of contaminated soil as determined from laboratory analytical results and LIF data. Because the LIF direct printouts indicate background signal noise ranging from 0-200 relative intensity (counts), a LIF reading of approximately 200 relative intensity (counts) was considered background for the site.

Figure 4.2a shows the highest analytical results and LIF readings from 5 to 15 feet bls. Shallow soil contamination (Figure 4.2a) appears to extend at least to CPT-11, CPT-12, and CPT-13 in the downgradient direction. CPT-7 has the greatest BTEX concentration (350,000 μ g/kg) in the shallow zone. Because the shallow zone is at least 5 feet above the groundwater table, BTEX detected at CPT-7 indicates that the former fuel lines and/or dispensers located along the northwestern side of the property may have contributed to the release. The zone of shallow residual LNAPL contamination in soil appears to be approximately 150 feet wide by 180 feet long.

Figure 4.2b presents LIF readings and BTEX and TVH analytical data from 15 to 25 feet bls at the Car Care Center Site from the August 1994 site investigation. Deep soil contamination may have resulted from mobile LNAPL movement in the aquifer and from adsorption of constituents onto the aquifer matrix. The zone of deep soil contamination (Figure 4.2b) appears to extend to CPT-3 and CPT-14 in the downgradient direction as indicated by soil analytical results. However, LIF data suggest that CPT-16, CPT-18, and CPT-23 also are impacted. Soil collected from CPT-9 at 18 feet bls had the highest BTEX (670,000 μ g/kg) concentrations at the site. However, BTEX concentrations were the same order of magnitude at CPT-7 and CPT-11. As a result, future remedial options should consider the residual LNAPL contamination in these areas. The zone of deep residual LNAPL contamination is approximately 300 feet wide by 300 feet long (Figure 4.2b).

Mobile LNAPL is present near the groundwater table as determined by liquid gasoline present within site monitoring wells. Furthermore, high LIF readings were measured near the water table in most CPT locations west of the Car Care Center building. The LIF data for CPT-7, CPT-12, and CPT-13 (Appendix A) suggests that a 7- to 10-foot thick band of LNAPL resides across the water table. This smear zone is created by groundwater fluctuations, which may trap LNAPL contamination both above and below the groundwater surface.

In addition, stratigraphic data from locations CPT-7, CPT-12, and CPT-13 (Appendix A) indicate the presence of clay lenses at approximately 13 feet bls. The measured depth to groundwater at these locations is approximately 17 feet bls. As a result, it appears that the clay lenses are retaining residual hydrocarbons above the groundwater table.

In August 1994, benzene was detected in shallow and deep soil samples from CPT-7, CPT-9, and CPT-11 in concentrations ranging from 3,600 μ g/kg to 20,000 μ g/kg. A low benzene concentration was detected at location CPT-14 (1.1 μ g/kg) at a shallow soil depth of 14.7 to 15.3 feet bls. This location is downgradient of the shallow residual LNAPL plume, but it is near the center of the deep residual LNAPL plume. The deep soil sample from 20 to 21.3 feet bls at CPT-14 contained BTEX at 160,000 μ g/kg. This demonstrates that at one time, mobile LNAPL, which originated in the shallow zone near the Car Care Center facility has migrated to deeper soils downgradient of its original location. The shallow soil contaminated zone is more limited in extent than the deeper zone. Because the shallow clay layer may be intermittent, a continuous perched water-bearing zone may not exist. As a result, mobile LNAPL may lack the mechanism to migrate laterally in the shallow zone. As a result, it migrates vertically under the influence of gravity, which has resulted in an accumulation near the water table.

4.2.1.2 Soil TVH Contamination

TVH was detected at all locations where BTEX was detected. No soil samples for TVH were collected in June 1996. Table 4.1 contains soil TVH data with a practical quantification limit of <110 µg/kg. A graphical representation of the August 1994 TVH data is provided in Figures 4.2a and 4.2b. Evergreen Analytical quantified TVH concentrations by comparison to a gasoline standard, which is the reported source of contamination. Typical total BTEX concentrations in fresh gasoline are approximately 14% to 21%. Evergreen Analytical quantified total BTEX and TVH in the soil samples. Then, Parsons ES calculated the average ratio of total BTEX to TVH observed in the soil samples in order to estimate the degree of LNAPL weathering which has occurred. Total BTEX percentages in soil ranged from 1.2% to 70%, with an average of 12%. Because TVH analyses only quantify lighter hydrocarbon fractions (generally compounds lighter than naphthalene), this comparison overestimates the fraction of BTEX within the LNAPL below the site. Thus, it is likely that the fuel below the site has weathered and BTEX soil concentrations have likely decreased over time.

4.2.2 Total Organic Carbon

TOC concentrations are used to estimate the amount of organic matter sorbed on soil particles or trapped in the interstitial passages of a soil matrix. The TOC concentration in the saturated zone is an important parameter used to estimate the amount of contaminant that could potentially be sorbed to the aquifer matrix. Sorption results in retardation of the contaminant plume relative to the average advective groundwater velocity. Parsons ES obtained two core samples from location CPT-24 for TOC analyses during the August 1994 site investigation. This location was suspected to be free from hydrocarbon contamination. TOC values range from 600 to 1,500 mg/kg (0.06 to 0.15 percent) (Table 4.1).

4.3 GROUNDWATER CHEMISTRY

4.3.1 Dissolved Contamination

Groundwater samples were collected in January 1994 during a previous site investigation (Baker, 1994). The BTEX data from that investigation are shown on Figure 4.3. During the intrinsic remediation site investigation conducted in August 1994, Parsons ES collected another round of groundwater samples to more thoroughly define the dissolved hydrocarbon plume. In addition to the August 1994 sampling event, Parsons ES collected a confirmation round of groundwater samples in June 1996 to provide data on contaminant loss and plume migration, to confirm the effect of biodegradation mechanisms on dissolved BTEX concentrations, and to evaluate the accuracy of the model predictions. Table 4.2 summarizes groundwater analytical data collected under both Parsons ES sampling events.

4.3.1.1 BTEX in Groundwater

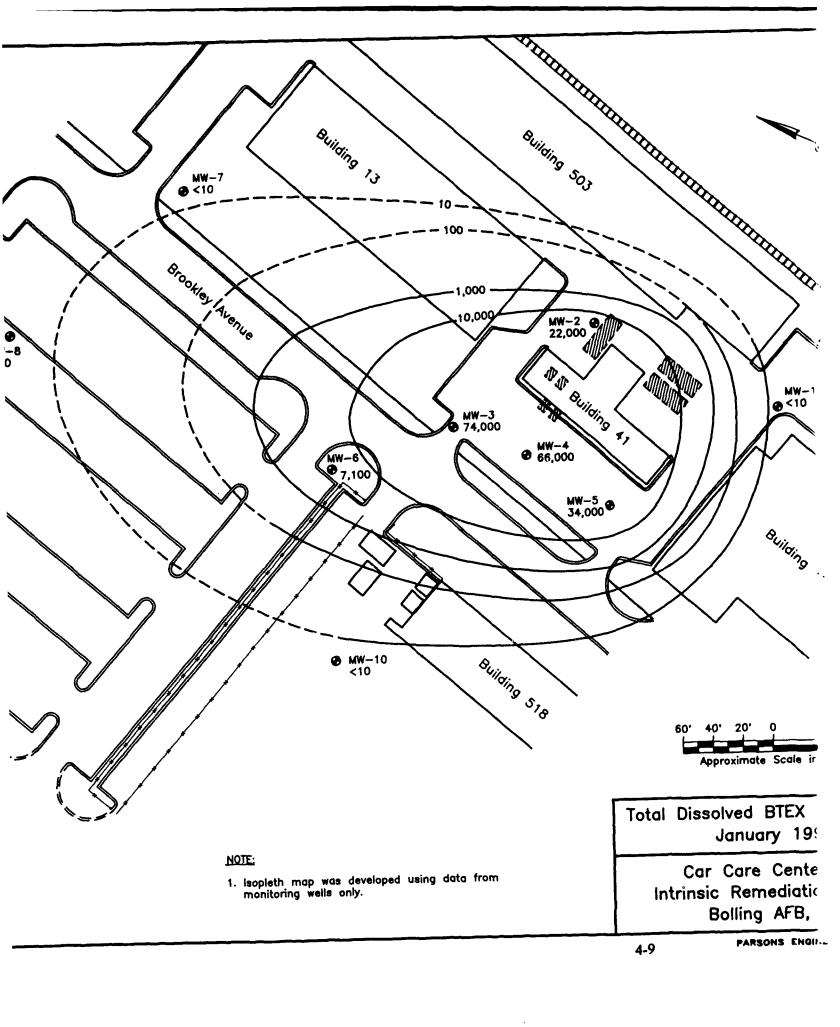

Figure 4.4 is a comparison of August 1994 and June 1996 observed total BTEX dissolved in groundwater. Isopleths are drawn based on the maximum concentration detected at each location. Two vertical concentration profiles also were generated for dissolved BTEX concentrations in August 1994, as well as for other dissolved constituents at the site. A cross-section location map showing concentration profile locations is shown in Figure 4.5. Figure 4.6 is a vertical profile of August 1994 BTEX isopleths along the centroid of the plume (cross-section D-D'). Figure 4.7 is a vertical profile of August 1994 BTEX isopleths perpendicular to plume migration (cross-section E-E').

Dissolved BTEX contamination is migrating to the northwest in the general direction of groundwater flow. However, the migration is slightly more to the west than indicated by previous reports (Baker, 1994). As defined by the 10 microgram per liter (μ g/L) total BTEX isopleth, the plume, in both 1994 and 1996, is greater than 630 feet long and approximately 300 feet at its widest. The apparent thickness of the BTEX plume is 25 to 30 feet, as defined by the $100-\mu$ g/L contour. The actual base of the surficial aquifer is not known. As indicated by the August 1994 vertical profile (Figure 4.6), the plume is migrating downward in the vicinity of CPT-11, MW-6, and CPT-18. Vertical migration is not apparent downgradient of CPT-18, but the plume geometry is not well defined beyond that point. As discussed in Section 3.3.2.1, the effects of vertical hydraulic gradients on contaminant plume migration are inconclusive.

Nineteen monitoring points and wells sampled at the site during August 1994 contained groundwater with reportable dissolved benzene concentrations above the DC Department of Consumer and Regulatory Affairs (DCRA) target cleanup value and the federal maximum contaminant level (MCL) of 5 μ g/L. Where detected in August 1994, benzene concentrations ranged from 0.6 μ g/L in CPT-22D to 44,000 μ g/L at CPT-11S. Toluene concentrations exceeded the DCRA criterion and federal MCL for dissolved toluene (1,000 μ g/L) in thirteen locations. Toluene concentrations ranged from 1.6 μ g/L at MW-9 and MW-10 to 57,000 μ g/L at CPT-11S. Most toluene concentrations were in the range of 10,000 to 35,000 μ g/L. Sample concentrations at thirteen locations exceeded the DCRA criterion and federal MCL (700 μ g/L) for ethylbenzene. In August 1994, ethylbenzene concentrations ranged from 0.6 μ g/L at

MW-7 to 3,000 μ g/L at MW-3. Generally, ethylbenzene was detected at lower concentrations than benzene or toluene. Finally, total xylene concentrations in August 1994 ranged from approximately 3 μ g/L at CPT-10D, MW-7, and MW-8, to 68,000 μ g/L at MW-2. The highest concentration was detected in MW-2, near the former 12,000-gallon gasoline UST that was recently removed. Total xylenes concentrations elsewhere generally ranged from 5,000 to 10,000 μ g/L. The DCRA target cleanup level and federal MCL for total xylenes is 10,000 μ g/L.

In June 1996, the highest concentration for each BTEX compound was detected in the sample from monitoring well MW-11 that was installed in 1996 to replace source area well MW-2 which was destroyed during site remediation activities. Seven of the thirteen monitoring points and wells sampled at the site contained groundwater with dissolved benzene concentrations above the DCRA criterion (and federal MCL). Where detected in June 1996, benzene concentrations ranged from 1.3 μ g/L in CPT-21S to 9,000 μ g/L at MW-11. Toluene concentrations exceeded the DCRA criterion and federal MCL for dissolved toluene at only MW-11 during the June 1996 sampling event. Toluene concentrations ranged from 0.6 μ g/L at CPT-21S to 25,000 μ g/L. Three sample concentrations exceeded the DCRA criterion and federal MCL for ethylbenzene in June 1996. Ethylbenzene concentrations ranged from 0.8 μ g/L at MW-1 to 2,300 μ g/L. In general, ethylbenzene was detected at higher concentrations than toluene. Where detected, total xylene concentrations ranged from approximately 0.5 μ g/L at CPT-20S, and MW-1 to 13,000 μ g/L at MW-11. The DCRA target cleanup level and federal MCL for total xylenes is 10,000 μ g/L.

Comparison of BTEX concentrations from the 1994 and 1996 sampling events suggest several possible trends. First, total BTEX concentration in the source area appears to be decreasing. Although a direct comparison of historical concentrations at a single source area location is not possible because all former source area monitoring wells and monitoring points were abandoned during remediation activities prior to the 1996 sampling event, a new source area well MW-11, was installed in early 1996 as a replacement for former MW-2. In August 1994, the total dissolved BTEX concentration in MW-2 was 100,000 μ g/L. For comparison, the total dissolved BTEX concentration detected in MW-11 from June 1996 was 49,300 μ g/L, less than half of the previous MW-2 concentration. Furthermore, a concentration of 49,300 μ g/L is less than 1994 concentrations in six of the seven sampled locations at the core of the plume (MW-2, MW-3, MW-4, CPT-2, CPT-9, CPT-10, and CPT-11). This suggests that the rate of BTEX dissolution from the source to the groundwater is decreasing with time.

A second observed trend is the decrease in total dissolved BTEX concentrations at cross-gradient sampling locations between 1994 and 1996. At the four cross-gradient wells MW-7, MW-8, MW-9, and MW-10, total dissolved BTEX dropped from low detected concentrations of less than 15 μ g/L in 1994 to below detection limits in 1996. This suggests that the rate of dissolved BTEX biodegradation exceeds the rate at which dissolved BTEX is migrating in the direction transverse to the primary groundwater flow direction.

A final trend suggests that the total dissolved BTEX plume is continuing to expand in the downgradient direction. The two furthest downgradient groundwater monitoring locations, CPT-21D and CPT-22D, both experienced large increases in total dissolved BTEX concentrations from 1994 to 1996: 9.55 μ g/L to 443 μ g/L at CPT-21D and 180

 μ g/L to 484 μ g/L at CPT-22D. This trend indicates that the rate of biodegradation is not capable of containing the influx of dissolved BTEX at the leading edge of the plume. As, would be expected, with total dissolved BTEX concentrations decreasing in the source area and increasing at the leading edge of the plume, a mix of increasing and decreasing concentrations is observed through the plume interior such as at location CPT-19D and CPT-20D.

4.3.2 Groundwater Geochemistry

Microorganisms obtain energy for cell production and maintenance by facilitating the transfer of electrons from electron donors to electron acceptors. This results in the oxidation of the electron donor and the reduction of the electron acceptor. Potential electron donors at the Car Care Center Site are natural organic carbon constituents and fuel hydrocarbon compounds. Fuel hydrocarbons are completely degraded or detoxified if they are utilized as the primary electron donor for microbial metabolism (Bouwer, 1992). Electron acceptors are elements or compounds that occur in relatively oxidized states and include DO (O₂), nitrate (NO₃⁻²), ferric iron (Fe⁺³), manganese dioxide (MnO₂), sulfate (SO₄⁻²), and carbon dioxide (CO₂). Microorganisms preferentially utilize electron acceptors while metabolizing fuel hydrocarbon (Bouwer, 1992). DO is utilized first by aerobic organisms as the primary electron acceptor. After the DO is consumed, anaerobic microorganisms use electron acceptors in the following order of preference: nitrate, ferric iron/ manganese dioxide, sulfate, and finally carbon dioxide.

Depending on the type of electron acceptors present (e.g., nitrate, sulfate, carbon dioxide), pH conditions, and redox potential, anaerobic biodegradation can occur by denitrification, ferric iron reduction, sulfate reduction, or methanogenesis. Other, less common anaerobic degradation mechanisms such as manganese reduction may dominate if the physical and chemical conditions in the subsurface favor use of these electron acceptors. Anaerobic destruction of the BTEX compounds is associated with the accumulation of fatty acids, production of methane, solubilization of iron and manganese, and reduction of nitrate and sulfate (Cozzarelli et al., 1990; Wilson et al., 1990). Environmental conditions and microbial competition will ultimately determine which processes will dominate. Vroblesky and Chapelle (1994) show that the dominant terminal electron accepting process can vary both temporally and spatially in an aquifer with fuel hydrocarbon contamination.

Car Care Center data for electron acceptors, from both sampling events, indicate intrinsic remediation of hydrocarbons in the shallow aquifer may be occurring by aerobic oxidation, denitrification, ferric iron reduction, manganese reduction, sulfate reduction, and methanogenesis. This is evidenced by significant changes in the groundwater geochemistry in comparison to background conditions found at the former Car Care Center. Areas of the site that have the greatest magnitude of change in the geochemical parameter concentrations generally correspond well with areas of low redox potentials and high BTEX concentrations. Table 4.3 summarizes groundwater geochemical data gathered during the intrinsic remediation demonstration in August 1994, and the one year update in June 1996 at Bolling AFB. Geochemical parameters for the Car Care Center Site are discussed in the following sections.

4.3.2.1 Dissolved Oxygen

DO concentrations were measured at monitoring points and existing monitoring wells during the August 1994 and June 1996 sampling events. Table 4.3 provides a summary of measured DO concentrations. Figure 4.8 provides two isopleth maps showing the distribution of DO concentrations in groundwater for August 1994 and June 1996. Figure 4.9 and Figure 4.10 are vertical profiles through the August 1994 DO plume. Comparison of Figure 4.4 with Figure 4.8, Figure 4.6 with Figure 4.9, and Figure 4.7 with Figure 4.10 shows graphically that areas with elevated total BTEX concentrations correlate with areas of reduced DO concentrations. The lowest observed DO concentration in August 1994 was 0.24 mg/L measured at CPT-11D. The lowest DO concentrations measured in the June 1996 sampling event was 0.05 mg/L measured at CPT-21D. Based on the 1994 background DO levels measured at MW-9 (5.2 mg/L), and a 1996 background DO of 7.5 mg/L (MW-9) it is likely that DO was and continues to be an important electron acceptor at the Car Care Center Site. This is a strong indication that aerobic biodegradation of the BTEX compounds is occurring at the site.

The anomalously high DO concentrations observed at CPT-19D and CPT-20D can be traced to the suspected perched water table in the immediate vicinity (Figure 3.1). The frequent watering of the grassy area around CPT-19 and CPT-20 and the presence of subsurface clay layers have caused the groundwater beneath the two points to become perched. This results from the additional water becoming trapped between the surface and the impermeable subsurface clay layer. Water used for landscaping purposes is usually high in DO because it is in contact with the atmosphere, therefore when water filters down through site soils it increases DO concentrations found in site groundwater.

The following equations describe the overall stoichiometry of aromatic hydrocarbon mineralization caused by microbial biodegradation. In the absence of microbial cell production, the oxidation (mineralization) of benzene to carbon dioxide and water is given by:

$$C_6H_6 + 7.5O_2 \rightarrow 6CO_{2(g)} + 3H_2O$$

Therefore, 7.5 moles of oxygen are required to metabolize 1 mole of benzene. On a mass basis, the ratio of oxygen to benzene is given by:

Molecular weights: Benzene

6(12) + 6(1) = 78 gm/mole

Oxygen

7.5(32) = 240 gm/mole

Mass Ratio of Oxygen to Benzene = 240/78 = 3.08:1

Therefore, in the absence of microbial cell production, 3.08 mg of oxygen are required to completely metabolize 1 mg of benzene.

Similar calculations can be completed for toluene (3.13 mg oxygen to 1 mg toluene), ethylbenzene (3.17 mg oxygen to 1 mg ethylbenzene), and xylenes (3.17 mg oxygen to 1 mg xylene). The average mass ratio of oxygen to total BTEX is thus 3.14:1. This means that approximately 0.32 mg of BTEX is mineralized for every 1.0 mg of DO consumed. As a conservative estimate, a background DO concentration

•

of 5 mg/L was assumed for the August 1994 sampling event. Based on this assumption, the shallow groundwater at this site had the capacity to assimilate 1.6 mg/L (1,600 µg/L) of total BTEX. Background DO for the June 1996 sampling event was estimated as 7 mg/L (based on DO concentration at MW-9). Using this estimate, the shallow groundwater at the former Car Care Center has the capacity to assimilate 2.2 mg/L (2,200 µg/L) of total BTEX during aerobic respiration. These are conservative estimates of the assimilative capacity of DO because microbial cell mass production was not taken into account by the stoichiometry shown above. This increase in aerobic assimilative capacity over two years, suggests that upgradient groundwater continues to provide significant amounts of dissolved oxygen, and possibly other electron acceptors, to the microbial population at the Car Care Center site.

When cell mass production is accounted for, the mineralization of benzene to carbon dioxide and water is given by:

$$C_6H_6 + 2.5O_2 + HCO_3^{-1} + NH_4^{-1} \rightarrow C_5H_7O_2N + 2CO_{2(q)} + 2H_2O$$

Note that only 2.5 moles of DO are required to mineralize 1 mole of benzene when cell mass production is taken into account. On a mass basis, the ratio of DO to benzene is given by:

Molecular weights: Benzene 6(12) + 6(1) = 78 gm/mole

Oxygen 2.5(32)= 80 gm/mole

Mass Ratio of Oxygen to Benzene = 80/78 = 1.03:1

Based on these stoichiometric relationships, 1.03 mg of oxygen are required to convert 1 mg of benzene into biomass, CO₂, and H₂O. Similar calculations can be made for toluene, ethylbenzene, and xylenes. Based on these calculations, approximately 0.97 mg of BTEX is converted into biomass and mineralized to carbon dioxide and water for every 1.0 mg of DO consumed. With an August 1994 background DO concentration of approximately 5 mg/L, the shallow groundwater at this site has the capacity to assimilate 4.8 mg/L (4,800 μ g/L) of total BTEX if microbial cell mass production is taken into account. Using a June 1996 background DO concentration of approximately 7 mg/L translates to the capacity to assimilate 6.8 mg/L (6,800 μ g/L) of total BTEX, if microbial cell mass production is taken into account. Because the contaminant plume has been present at the site for many years, the only location where microbial cell mass is likely to be increasing is at the leading edge of the plume which is still advancing.

4.3.2.2 Nitrate/Nitrite

Concentrations of nitrate + nitrite (as N) were measured at groundwater monitoring points and at existing monitoring wells in August 1994 and June 1996. Table 4.3 shows these concentrations. The observed nitrate concentrations were generally on the order of 10 to 100 times larger than nitrite concentrations. As a result, only nitrate concentrations were considered to be an important indicator of ongoing denitrification at the site. In August 1994, high nitrate concentrations were observed at MW-7 (18 mg/L) and MW-10 (13 mg/L). Both of these wells have relatively low (close to

background) BTEX concentrations and high concentrations of dissolved oxygen. More moderate nitrate concentrations were observed at CPT-10D (4.7 mg/L) and MW-9 (2.0 mg/L) which also have low BTEX concentrations and aerobic conditions. June 1996 nitrate + nitrite data, correspond very closely to data collected in 1994. Concentrations of nitrate observed during the June 1996 sampling event, ranged from 0.056 mg/L to 17.2 mg/L. Figure 4.11 provides two isopleth maps showing the distribution of nitrate + nitrite (as N) in groundwater for both the August 1994 and June 1996. Comparison with Figure 4.4 shows graphically that areas with elevated total BTEX concentrations have decreased nitrate + nitrite concentrations. Figures 4.12 and 4.13 are vertical profiles of nitrate concentrations from August 1994 data along cross-sections D-D' and E-E', respectively.

The low nitrate concentrations observed in the center of the BTEX plume indicate that anaerobic biodegradation of BTEX is occurring through the microbially mediated process of denitrification. Nitrate reduction may be a significant removal mechanism if actual background nitrate concentrations are above 10 mg/L as nitrogen (N). However, as a conservative assumption, a background nitrate concentration of 5.0 mg/L as N for both sampling events was utilized in this analysis to estimate assimilative capacity by denitrification. Since the nitrate concentrations in Table 4.3 are reported as mg/L as N, the values must be multiplied by 4.42 to be converted to mg/L as NO₃.

In the absence of microbial cell production, the biodegradation of benzene to carbon dioxide and water by the denitrification process is given by:

$$6NO_3 + 6H' + C_6H_6 \rightarrow 6CO_{2(g)} + 6H_2O + 3N_{2(g)}$$

Based on this relationship, 6 moles of nitrate are required to mineralize 1 mole of benzene. On a mass basis, the ratio of nitrate to benzene is given by:

Molecular weights:

Benzene

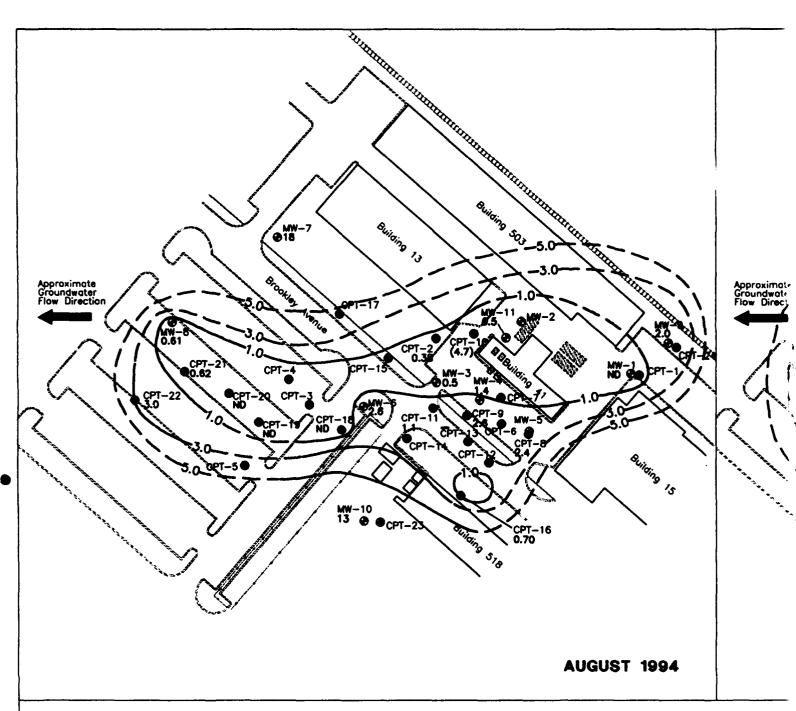

6(12) + 6(1) = 78 gm/mole

Nitrate

14+3(16) = 62 gm/mole

Mass ratio of nitrate to benzene = 6(62)/78 = 4.77:1

In the absence of microbial cell production, 4.77 mg of nitrate are required to completely mineralize 1 mg of benzene. Similar calculations can be completed for toluene (4.85 mg nitrate to 1 mg toluene), ethylbenzene (4.92 mg nitrate to 1 mg ethylbenzene), and the xylenes (4.92 mg nitrate to 1 mg xylene). The average mass ratio of nitrate consumed to total BTEX degraded is 4.86:1. This means that approximately 0.20 mg of BTEX is mineralized for every 1.0 mg of nitrate consumed. With an assumed background nitrate concentration of 22.1 mg/L as NO₁ (5 mg/L as N multiplied by the conversion factor of 4.42), for both August 1994 and June 1996, the shallow groundwater at this site has the capacity to assimilate 4.4 mg/L (4,400 μ g/L) of total BTEX during denitrification. This is a very conservative estimate of the assimilative capacity of nitrate because microbial cell mass production has not been taken into account by the stoichiometry shown above (Section 4.3.2.1). The similarity between August 1994 and June 1996 site nitrate concentrations and denitrification assimilative capacities suggest that denitrification remains an important biodegradation mechanism and that nitrate is being replenished at the site via upgradient groundwater sources.

4.3.2.3 Ferrous Iron

Ferrous iron concentrations were measured at groundwater monitoring points and at existing monitoring wells in August 1994 and June 1996. Table 4.3 summarizes ferrous iron concentrations observed at the site. Figure 4.14 provides two isopleth maps comparing the distribution of ferrous iron in groundwater from the two sampling Figures 4.15 and 4.16 are vertical profiles of observed ferrous iron events. concentrations from the August 1994 site investigation at the Car Care Center Site. Comparison of Figures 4.14 and 4.4 shows graphically that the areas with the highest ferrous iron concentration also have the highest BTEX concentration. This suggests that ferric iron is being reduced to ferrous iron during biodegradation of BTEX The highest measured ferrous iron concentration in August 1994, 12 mg/L, was detected at CPT-19D. This location is downgradient of the areas that contain the highest BTEX concentrations. Ferrous iron is possibly being converted in the plume center, then is migrating downgradient with the groundwater. High ferrous iron concentrations were also detected in August 1994 at MW-2 (8.4 mg/L), MW-3 (6.6 mg/L), MW-4 (6.1 mg/L), CPT-11D (8.1 mg/L), and CPT-16D (8.4 mg/L), all of which are located near the center of the BTEX plume. The elevated ferrous iron concentration in MW-1 (8.9 mg/L) was inconsistent with the previous trend, as BTEX concentrations are low at this location. Background levels of ferrous iron are generally at or below 0.1 mg/L, as measured at wells with little or no known BTEX contamination.

In June 1996, the highest measured ferrous iron concentration of 20.3 mg/L was detected at CPT-20D. Additional high ferrous iron concentrations were detected in June 1996 at CPT-19D (16.0 mg/L), MW-11 (11.4 mg/L), and CPT-21S (10.5 mg/L). All of these elevated ferrous iron concentrations were observed in sampling locations which are located just downgradient, or in the area of the highest BTEX concentrations observed in groundwater. The increased ferrous iron concentration at MW-1, observed in both 1994 and 1996 sampling events, could suggest an alternate source of ferrous iron just upgradient from MW-1. Measurements of DO, nitrate, and BTEX in groundwater samples from MW-1 suggest that an upgradient source of fuel hydrocarbons, not related to the Car Care Center site, could exist. However, the significant decrease in dissolved BTEX concentrations at MW-1 suggest that this unknown upgradient source is being biodegraded at similar rates as the contaminant plume at the former Car Care Center.

Background levels of ferrous iron are generally at or below 0.1 mg/L, as measured at wells with little or no known BTEX contamination. August 1994 and June 1996 ferrous iron plumes (Figure 4.14) suggest that iron reduction is still a very important biodegradation mechanism at the site, because ferrous iron concentrations continue to be elevated in the groundwater just downgradient from the source area near Car Care Center.

Ferrous Iron Isopleth Maps for Groundwater

Car Care Center Site Intrinsic Remediation EE/CA Bolling AFB, DC

હ

The following equations describe the overall stoichiometry of benzene degradation by iron reduction. In the absence of microbial cell production, the mineralization of benzene by iron reduction is given by:

$$60H^{+} + 30Fe(OH)_{3(a)} + C_{6}H_{6} \rightarrow 6CO_{2} + 30Fe^{2+} + 78H_{2}O$$

Therefore, 30 moles of ferric iron are required to metabolize 1 mole of benzene. On a mass basis, the ratio of ferric iron to benzene is given by:

Molecular weights: Benzene

6(12) + 6(1) = 78 gm/mole

Ferric Iron

30(106.85) = 3200 gm/mole

Mass ratio of ferric iron to benzene = 3200/78 = 41.0:1

Therefore, in the absence of microbial cell production, 41.0 mg of ferric iron are required to completely metabolize 1 mg of benzene. Alternatively, the mass ratio of ferrous iron produced during respiration to benzene degraded can be calculated and is given by:

Molecular weights:

Benzene

6(12) + 6(1) = 78 gm/mole

Ferrous Iron

30(55.85) = 1675 gm/mole

Mass ratio of ferrous iron to benzene = 1675/78 = 21.5:1

Therefore, 21.5 mg of ferrous iron are produced during mineralization of 1 mg of benzene.

Similar calculations can be completed for toluene (21.86 mg of Fe²⁺ produced during mineralization of 1 mg of toluene), ethylbenzene (22 mg of Fe²⁺ produced during mineralization of 1 mg of ethylbenzene), and the xylenes (22 mg of Fe²⁺ produced during mineralization of 1 mg of xylene). The average mass ratio of Fe²⁺ produced during total BTEX mineralization is thus 21.8:1. This means that approximately 1 mg of BTEX is mineralized for every 21.8 mg of Fe²⁺ produced.

The highest Fe^{2+} concentration observed in August 1994 was 12 mg/L. This suggests that the shallow groundwater at this site has the capacity to assimilate 0.55 mg/L (550 µg/L) of total BTEX during iron reduction. In June 1996, the highest ferrous iron concentration observed at the Car Care Center was 20.3 mg/L, suggesting that the groundwater has the capacity to assimilate 0.93 mg/L (or 930 µg/L). These are conservative estimates of the assimilative capacity of iron because microbial cell mass production has not been taken into account by the stoichiometry shown above (Section 4.3.2.1). In addition, this calculation is based on observed ferrous iron concentrations and not on the amount of ferric hydroxide available in the aquifer. Therefore, iron assimilative capacity could be much higher.

4.3.2.4 Sulfate

Sulfate concentrations were measured at groundwater monitoring points and at existing monitoring wells in August 1994 and June 1996. Table 4.3 summarizes sulfate concentrations measured at the site. Figure 4.17 provides two isopleth maps showing the distribution of sulfate in groundwater in the 1994 and 1996 sampling events. Figures 4.18 and 4.19 are vertical profiles of the dissolved sulfate plume in August 1994. Comparison of Figures 4.17 and 4.4 shows graphically that the areas with the lowest sulfate concentrations have the highest BTEX concentrations. This suggests that the sulfate is being reduced during biodegradation of BTEX compounds. In August 1994, the highest measured sulfate concentration was 91 mg/L measured at MW-7. Significant sulfate concentrations were also observed at CPT-8D (65 mg/L), CPT-10D (56 mg/L), and CPT-21D (62 mg/L) which are located at the fringes of the BTEX plume. August 1994 background sulfate concentrations ranged from 50 mg/L to approximately 91 mg/L. As a conservative estimate, the background sulfate concentration for the site was assumed to be 50 mg/L. Complete sulfate depletion was noted only at MW-4 (0.4 mg/L), which is one of the most contaminated wells. Generally, sulfate concentrations were reduced to approximately 12 mg/L near the center of the BTEX plume.

The highest measured sulfate concentration in June 1996, 83 mg/L, was also measured at MW-7. Sulfate concentrations were also high at MW-9 (73 mg/L), and MW-10 (54 mg/L). A conservative background sulfate concentration of 54 mg/L, from MW-10, was assumed from June 1996 data. Almost complete sulfate depletion was noted at MW-11 (0.97 mg/L), CPT-20D (0.95 mg/L), and CPT-19D (0.88 mg/L).

Hydrogen sulfide is an end product of the sulfate reduction reaction. In August 1994, concentrations of hydrogen sulfide (Table 4.3) were measured in site monitoring wells and monitoring points. However, hydrogen sulfide was not detected at the site. This result may be due to the strong affinity of certain aquifer matrices for the sulfide ion. High levels of iron and manganese compounds are generally contained within the aquifer matrices. The sulfide ion will react with iron and manganese to form insoluble metallic sulfides. As a result, the absence of hydrogen sulfide in site groundwater does not negate the evidence of sulfate reduction. Hydrogen sulfide was not measured in groundwater samples taken from the site during the June 1996 sampling event.

The following equations describe the overall stoichiometry of BTEX oxidation by sulfate reduction caused by anaerobic microbial biodegradation. In the absence of microbial cell production, the biodegradation of benzene is given by:

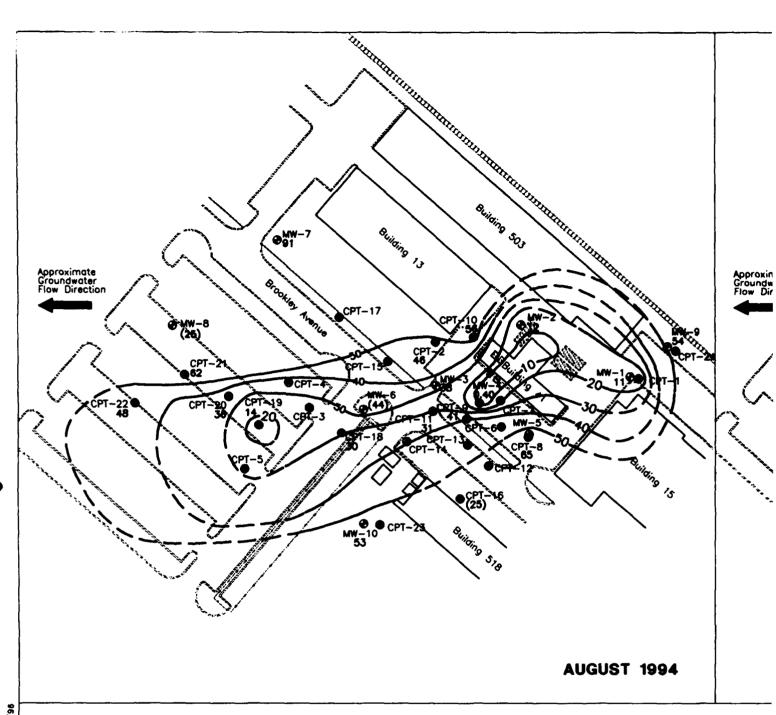

$$7.5H^{+} + 3.75SO_{4}^{2} + C_{6}H_{6} \rightarrow 6CO_{2(g)} + 3.75H_{2}S_{(g)} + 3H_{2}O_{2(g)}$$

Therefore, 3.75 moles of sulfate are required to mineralize 1 mole of benzene. On a mass basis, the ratio of sulfate to benzene is given by:

Molecular weights: Benzene 6(12) + 6(1) = 78 gm/mole

Sulfate 32.06+4(16) = 96.06 gm/mole

Mass ratio of sulfate to benzene = 3.75(96.06)/78 = 4.6:1

LEGEND

(4)

Therefore, in the absence of microbial cell production, 4.6 mg of sulfate are required to completely mineralize 1 mg of benzene. Similar calculations can be completed for toluene (4.7 mg sulfate to 1 mg toluene), ethylbenzene (4.75 mg sulfate to 1 mg ethylbenzene), and the xylenes (4.75 mg sulfate to 1 mg xylene). The average mass ratio of sulfate to total BTEX is thus 4.7:1. This means that approximately 0.21 mg of BTEX is mineralized for every 1.0 mg of sulfate consumed. Assuming a background sulfate concentration of 50 mg/L in August 1994, the shallow groundwater at this site has the capacity to assimilate 10 mg/L (10,000 µg/L) of total BTEX during sulfate reduction. In June 1996, a background sulfate concentration of 54 mg/L was observed, suggesting that the groundwater at the site has the capacity to assimilate 11 mg/L (11,000 µg/L) of total BTEX during sulfate reduction. Again, these are very conservative estimates of the assimilative capacity of sulfate because microbial cell mass production has not been taken into account by the stoichiometry shown above Comparison of August 1994 and June 1996 site sulfate concentrations suggest, once again, that sulfate reduction continues to be an important biodegradation mechanism at the Car Care Center.

4.3.2.5 Methane

Methane concentrations were measured at groundwater monitoring points and at existing monitoring wells in January 1995 and June 1996. Table 4.3 summarizes the measured methane concentrations. No observable trends could be discerned from January 1995 methane data, but the monitoring points (i.e., CPT-19, 20, and 21) downgradient from the highest BTEX concentrations were not sampled. Consequently, no general conclusions could be drawn about the importance of methanogenic BTEX biodegradation at the site. However, June 1996 methane data for the Car Care Center site, show significant increases in groundwater methane concentrations downgradient from the source area. Figure 4.20 presents an isopleth map showing the distribution of methane in groundwater based on data collected in June 1996. Comparison of Figure 4.20 with Figure 4.4 shows graphically that the core of the dissolved BTEX plume downgradient from the source generally correlates with center of the area with elevated methane concentration.

The following equations describe the overall stoichiometry of benzene oxidation by methanogenesis where carbon dioxide is utilized as the terminal electron acceptor. In the absence of microbial cell production, the mineralization of benzene is given by:

$$C_6H_6 + 4.5H_2O \rightarrow 2.25CO_2 + 3.75CH_4$$

The mass ratio of methane produced during respiration to benzene degraded can be calculated and is given by:

Molecular weights: Benzene 6(12) + 6(1) = 78 gm/mole

Methane 12 + 4(1) = 16 gm/mole

Mass ratio of methane to benzene = 3.75(16)/78 = 0.77:1

Therefore, 0.77 mg of methane is produced during mineralization of 1 mg of benzene.

Similar calculations can be completed for toluene (0.78 mg of methane produced during mineralization of 1 mg of toluene), ethylbenzene (0.79 mg of methane produced during mineralization of 1 mg of ethylbenzene), and the xylenes (0.79 mg of methane produced during mineralization of 1 mg of xylene). The average mass ratio of methane produced during total BTEX mineralization is 0.78:1. This means that approximately 1 mg of BTEX is mineralized for every 0.78 mg of methane produced. In June 1996, the highest measured methane concentration was 9.1 mg/L (CPT-20D). This suggests that the shallow groundwater at this site has the capacity to assimilate up to 11.7 mg/L (11,700 μ g/L) of total BTEX during methanogenesis. Again, this is a conservative estimate of the assimilative capacity of methanogenesis because microbial cell mass production is not taken into account by the stoichiometry shown above (Section 4.3.2.1). In addition, these calculations are based on observed methane concentrations and not on the amount of carbon dioxide available in the aquifer. Therefore, methanogenic assimilative capacity could be much higher.

4.3.2.6 Manganese

Soluble manganese (Mn²⁺) concentrations were measured at groundwater monitoring points and at existing monitoring wells in June 1996. summarizes soluble manganese concentrations observed at the site. Figure 4.20 presents an isopleth map showing the distribution of Mn²⁺ in groundwater. Comparison of Figures 4.20 and 4.4 shows graphically that the areas with the highest soluble manganese concentration also have the highest BTEX concentration. This suggests that insoluble forms of manganese (i.e., manganese dioxide) is being reduced to Mn² The highest measured Mn2+ during biodegradation of BTEX compounds. concentration, 13.6 mg/L, was detected at CPT-21D. This location is downgradient of the areas that contain the highest BTEX concentrations. Similar to ferrous iron, Mn²⁺ is possibly being produced in the plume center, then is migrating downgradient with the groundwater. In June 1996, elevated soluble manganese concentrations also were detected at MW-11 (7.9 mg/L), CPT-22D (8.8 mg/L), and CPT-20D (5.8 mg/L). Background levels of soluble manganese are approximately 0.1 mg/L, as measured at MW-9, which is upgradient from the source area at the Car Care Center.

The following equations describe the overall stoichiometry of benzene oxidation by manganese reduction where carbon dioxide is utilized as the terminal electron acceptor. In the absence of microbial cell production, the mineralization of benzene is given by:

$$30H^+ + 15 \text{ MnO}_2 + \text{C}_6H_6 \rightarrow 6\text{CO}_2 + 15\text{Mn}^{2+} + 18\text{H}_2\text{O}$$

Therefore, 15 moles of soluble manganese are produced during the metabolism of 1 mole of benzene. The mass ratio of soluble manganese produced during respiration to benzene degraded can be calculated and is given by:

Molecular weights: Benzene 6(12) + 6(1) = 78 gm/mole

 Mn^{2+} 55 = 55 gm/mole

Mass ratio of Mn^{2+} to benzene = 15(55)/78 = 10.6:1

Therefore, 10.6 mg of Mn²⁺ is produced during mineralization of 1 mg of benzene.

Similar calculations can be completed for toluene (10.7 mg of Mn^{2+} produced during mineralization of 1 mg of toluene), ethylbenzene (11.4 mg of Mn^{2+} produced during mineralization of 1 mg of ethylbenzene), and the xylenes (11.4 mg of Mn^{2+} produced during mineralization of 1 mg of xylene). The average mass ratio of Mn^{2+} produced during total BTEX mineralization is 11.0:1. On a mass basis, this translates to approximately 11.0 mg of soluble manganese produced for each 1 mg of total BTEX metabolized. Given a background soluble manganese concentration of approximately 0.1 mg/L and a maximum detected soluble manganese concentration in the source area of 13.6 mg/L, the shallow groundwater has the capacity to assimilate approximately 1.2 mg/L (1,200 μ g/L) of total BTEX through manganese reduction. This assimilative capacity is conservative estimate because calculations are based on observed soluble manganese concentrations and not on the amount of manganese dioxide available in the aquifer and solid soil matrix. Therefore, manganese assimilative capacity could be much higher.

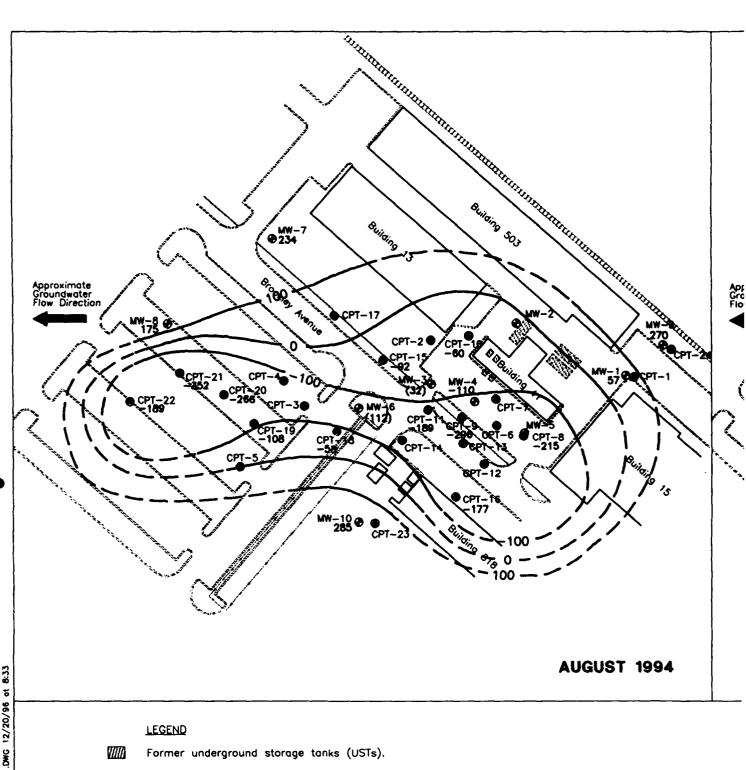

4.3.2.7 Reduction/Oxidation Potential

Redox potentials were measured at groundwater monitoring points and at existing monitoring wells in August 1994 and June 1996. Redox potential is a measure of the relative tendency of a solution to accept or transfer electrons. The redox potential of a groundwater system depends on which electron acceptor is being reduced by microbes during BTEX oxidation. The redox potential at the Car Care Center Site during the August 1994 sampling event ranged from 285 millivolts (mV) to -477 mV. June 1996 redox measurements ranged from 176 mV to -154 mV. Table 4.3 summarizes available redox potential data. Figure 4.21 provides two maps that graphically illustrate the distribution of redox potentials for both sampling events. Figures 4.22 and 4.23 indicate the vertical redox profiles at the Car Care Center Site for data collected during August 1994. August 1994 redox values decreased to values below -200 mV in the vicinity of CPT-08, CPT-09, CPT-20, and CPT-21. In June 1996, areas at the site with low redox potentials coincide with areas of low DO, nitrate, and sulfate concentrations and elevated BTEX, ferrous iron, and methane concentrations.

4.3.2.8 Alkalinity and Carbon Dioxide Evolution

Carbon dioxide is produced during the bioremediation of petroleum hydrocarbons. In aquifers that have carbonate minerals as part of the matrix, carbon dioxide forms carbonic acid, which dissolves these minerals, increasing the alkalinity of the groundwater. An increase in alkalinity (measured as CaCO₃) in an area with BTEX concentrations elevated above background conditions can be used to infer the amount of petroleum hydrocarbon destroyed through aerobic respiration, denitrification, manganese reduction, ferric iron reduction, and sulfate reduction. In addition, carbon dioxide produced in these aerobic and anaerobic reactions can be cycled in the methanogenic reactions to continue BTEX biodegradation through methanogenesis.

Free carbon dioxide was measured in groundwater samples collected in June 1996. These measurements are summarized in Table 4.3 and illustrated for the shallow groundwater in Figure 4.24. Carbon dioxide evolution above background concentrations, approximately 100 mg/L, is occurring as a result of combined aerobic

and anaerobic biodegradation processes. A direct estimation of the aquifer assimilative capacity based on carbon dioxide evolution is not possible because of the complex However, total alkalinity (as CaCO₃) also was carbonate/bicarbonate balance. measured in groundwater samples collected in both August 1994 and June 1996. These measurements are summarized in Table 4.3. June 1996 total alkalinity data also is illustrated for shallow groundwater in Figure 4.21. Alkalinity is a measure of the ability of groundwater to buffer changes in pH caused by the addition of biologically generated acids. Furthermore, alkalinity can be used in certain situations to estimate the assimilative capacity of groundwater (Wiedemeier et al., 1994). In August 1994, total alkalinity at the site ranged from < 5.0 mg/L to approximately 266 mg/L. In June 1996, total alkalinity at the Car Care Center ranged from 20 mg/L to approximately 1,100 mg/L. This range of alkalinity is sufficient to buffer potential changes in pH caused by biologically mediated BTEX oxidation reactions; therefore, it supports the inference that aerobic and/or anaerobic biodegradation processes are occurring without detrimental shifts in pH. At least, sufficient alkalinity and observed increases in carbon dioxide levels are supportive of an amenable environment for intrinsic biodegradation as observed by evolved carbon dioxide. Additionally, comparison of alkalinity concentrations and elevated BTEX concentrations (Figures 4.24 and 4.4) suggest that increased carbonate concentrations could be directly related to increased carbon dioxide concentrations from the mineralization of the BTEX compounds via natural attenuation processes.

4.3.2.9 pH

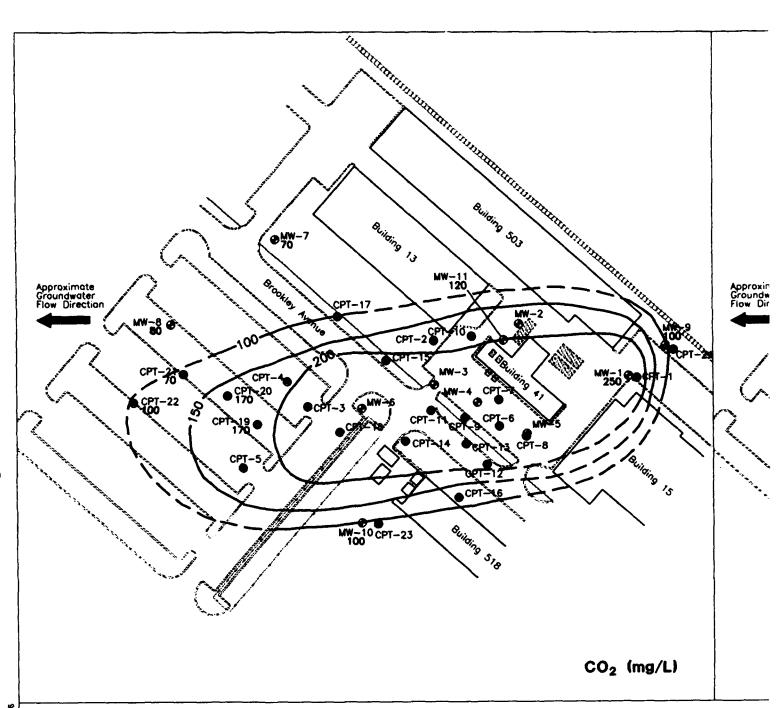

pH was measured at groundwater monitoring points and existing monitoring wells in August 1994 and June 1996. These measurements are summarized in Table 4.3. The pH of a solution is the negative logarithm of the hydrogen ion concentration [H⁺]. Groundwater pH at the Car Care Center Site ranged from 4.46 to 6.62 in August 1994, and from 4.50 to 7.70 in June 1996. These are acceptable ranges for BTEX-degrading microbes. Usually, pH values between 4.5 and 5.5 are generally considered to be less than optimal for BTEX biodegradation. However, the groundwater geochemistry discussed in previous sections suggests that strong natural attenuation patterns occur at the site; therefore, it is doubtful that groundwater pH is impeding biodegradation processes.

4.3.2.10 Temperature

Groundwater temperature was measured at groundwater monitoring points and existing monitoring wells in August 1994 and June 1996. Table 4.3 summarizes groundwater temperature readings. Temperature affects the types and growth rates of bacteria that can be supported in the groundwater environment, with higher temperatures generally resulting in higher growth rates. Temperatures in the shallow saturated zone varied from 20.0 degrees Celsius (°C) to 25.6°C in August 1994, and from 18.3°C to 21.9°C in June 1996. These ranges are relatively high temperatures for shallow groundwater, suggesting that bacterial growth rates could be high.

4.3.3 Expressed Assimilative Capacity

The data presented in the preceding sections suggest that mineralization of BTEX compounds is occurring through the microbially mediated processes of aerobic

respiration, denitrification, iron reduction, sulfate reduction, manganese reduction and methanogenesis. Based on the stoichiometry presented in these sections and August 1994 groundwater data, the expressed BTEX assimilative capacity of groundwater at the Car Care Center Site is at least 16,550 µg/L (Table 4.4). In June 1996, the expressed BTEX assimilative capacity of groundwater at the Car Care Center Site is at least 31,430 µg/L (Table 4.4). The calculations presented in these earlier sections are conservative because they do not account for microbial cell mass production. In addition, the measured concentrations of ferrous iron, soluble manganese, and methane may not be the maximum achievable. The highest measured dissolved total BTEX concentration observed in August 1994 at the site was 110,000 µg/L (measured at CPT-11S). This concentrations is just below the maximum solubility of BTEX from fresh gasoline reported to be approximately 135,000 μ g/L (Wiedemeier et al., 1994). In June 1996, the highest total BTEX concentration of 49,300 µg/L was measured at MW-11. As a result, the calculated expressed assimilative capacities of groundwater are less than the maximum dissolved BTEX concentration for their respective years. Additional modeling activities are presented in Section 5 to evaluate the effect to the nearest potential downgradient receptor point (the Potomac River) located 0.5 mile downgradient from the site.

SECTION 5

GROUNDWATER MODELING

5.1 GENERAL OVERVIEW AND MODEL DESCRIPTION

In order to help estimate degradation rates for dissolved BTEX compounds at the former Car Care Center Site (Building 41) and to help predict the future migration of these compounds, Parsons ES modeled the fate and transport of the dissolved BTEX plume. The modeling effort had three primary objectives: i) to predict the future extent and concentration of the dissolved contaminant plume by modeling the combined effects of advection, dispersion, sorption, and biodegradation; 2) to assess the possible risk to potential downgradient receptors; and 3) to provide technical support for the natural attenuation remedial option at post-modeling regulatory negotiations. The model was developed using site-specific data and conservative assumptions about governing physical and chemical processes. Due to the conservative nature of the model input, the reduction in contaminant mass resulting from the process of natural attenuation is expected to exceed model predictions. This analysis is not intended to represent a baseline assessment of potential risks posed by site contamination.

The Bioplume II model was used to estimate the potential for dissolved BTEX migration and degradation by naturally occurring mechanisms operating at the former Car Care Center Site (Building 41). The Bioplume II code incorporates advection, dispersion, sorption, and biodegradation to simulate contaminant plume migration and degradation. The model is based upon the USGS Method of Characteristics (MOC) two-dimensional (2-D) solute transport model of Konikow and Bredehoeft (1978). The model was modified by researchers at Rice University to include a biodegradation component that is activated by a superimposed DO plume. Based on the work of Borden and Bedient (1986), the model assumes a reaction between DO and BTEX that is instantaneous relative to the advective groundwater velocity. Bioplume II solves the USGS 2-D solute transport equation twice, once for hydrocarbon concentrations in the aquifer and once for a DO plume. The two plumes are combined using superposition at every particle move to simulate the instantaneous, biologically-mediated, reaction between hydrocarbons and oxygen.

In recent years, it has become apparent that anaerobic processes such as denitrification, iron reduction, sulfate reduction, and methanogenesis can be important BTEX degradation mechanisms (Grbic'-Galic', 1990; Beller et al., 1992; Edwards et al., 1992; Edwards and Grbic'-Galic', 1992, Grbic'-Galic' and Vogel, 1987; Lovley et al., 1989; Hutchins, 1991). As evidenced from the data specified in Section 4, anaerobic biodegradation is occurring at the former Car Care Center Site. However, as a conservative estimate only oxygen and nitrate were used as electron acceptors during Bioplume II modeling.

In order to verify the results of the Bioplume II model, Parsons ES calculated a first-order decay coefficient using methods specified by Wiedemeier et al. (1994) and site specific data. An analytical model (Bear, 1979) was utilized that incorporates one-dimensional advection, dispersion, retardation, and first-order decay. A comparison between numerical and analytical model results was then performed to validate the Bioplume II input parameters and to compare Bioplume II and analytical model output results. A discussion of model results are provided in Section 5.6.1. The analytical model is provided in Appendix D. The following subsections discuss in more detail the model setup, input parameters and assumptions, model calibration, and simulation results.

5.2 CONCEPTUAL MODEL DESIGN AND ASSUMPTIONS

Prior to developing a groundwater model, it is important to determine if sufficient data are available to provide a reasonable estimate of aquifer conditions. In addition, it is important to ensure that any limiting assumptions can be justified. The most important assumption made when using the Bioplume II model is that oxygen-limited biodegradation is occurring at the site. The Bioplume II model assumes that the limiting factors for biodegradation are: 1) the presence of an indigenous hydrocarbon degrading microbial population, and 2) sufficient background electron acceptor concentrations. Data and information presented in Sections 3 and 4 suggest that oxygen, nitrate, ferric hydroxide, sulfate, and carbon dioxide (methanogenesis) are being used as electron acceptors for aerobic and anaerobic biodegradation. To be conservative, only oxygen and nitrate were used as electron acceptors in the Bioplume II model presented herein. The rate of reaction for denitrification is relatively fast, as compared to the advective groundwater velocity. As a result, the instantaneous reaction assumption is valid.

Based on the data presented in Section 3, the shallow saturated zone was conceptualized and modeled as a shallow unconfined aquifer composed of silty sand (Figures 3.3, 3.4, and 3.5). The depth of the saturated zone was conceptualized at the site to be 30 feet. The actual thickness is not known with certainty; however, the base of the aquifer may be 700 to 1,000 feet bls. Given the contaminated zone is only 25 to 30 feet thick (Section 4.3.1.1), Parsons ES utilized a saturated thickness of 30 feet as a reasonable estimate for the thickness of the model domain. Bioplume II assumes a constant solute concentration throughout the entire depth of the cell.

The use of a 2-D model is appropriate at the former Car Care Center Site (Building 41) because the saturated interval is relatively homogenous, and the local flow system, as defined by gradients, will likely minimize significant downward vertical migration of dissolved BTEX contamination. The vertical BTEX concentration profiles (Figure 4.6 and 4.7) suggest minor downward migration may be occurring in the vicinity of the source area. However, this may be due to diffusion of BTEX away from the source area, because a downward migration trend is not prevalent throughout the remaining sections of the plume. Because residual and mobile LNAPL contamination still exists at the site, model simulations include continuing sources of dissolved BTEX contamination.

r)

5.3 INITIAL MODEL SETUP

Where possible, the initial setup for this model was based on site data. Where site-specific data were not available (e.g., effective porosity, reaeration coefficient), reasonable assumptions for the types of materials comprising the shallow aquifer were made based on widely accepted literature values. The following sections describe the basic model setup. A sensitivity analysis was performed for the input parameters, known to have the most significant effect on model results, by varying input values. Those Bioplume II model parameters that were varied during model calibration are discussed in Section 5.4.2.1.

5.3.1 Grid Design and Boundary Conditions

The Bioplume II model assumes a non-bending longitudinal axis along the primary direction of groundwater flow. Because the Bioplume II model was based on the finite difference numerical procedure, the model domain was subdivided in to evenly spaced grids. The maximum grid size for the Bioplume II model is limited to 20 columns by 30 rows and the dimension of each column and row can range from 0.1 to 999.9 feet. A grid size of 20 cells (transverse or x-direction) by 30 cells (longitudinal or y-direction) was used to model the former Car Care Center Site (Building 41). Each grid cell was 30 feet wide by 35 feet long (i.e., the grid was oriented so that the longest dimension was parallel to the overall direction of groundwater flow). The model grid covers an area of 630,000 square feet, or approximately 14.5 acres. The full extent of the model grid is indicated on Figure 5.1.

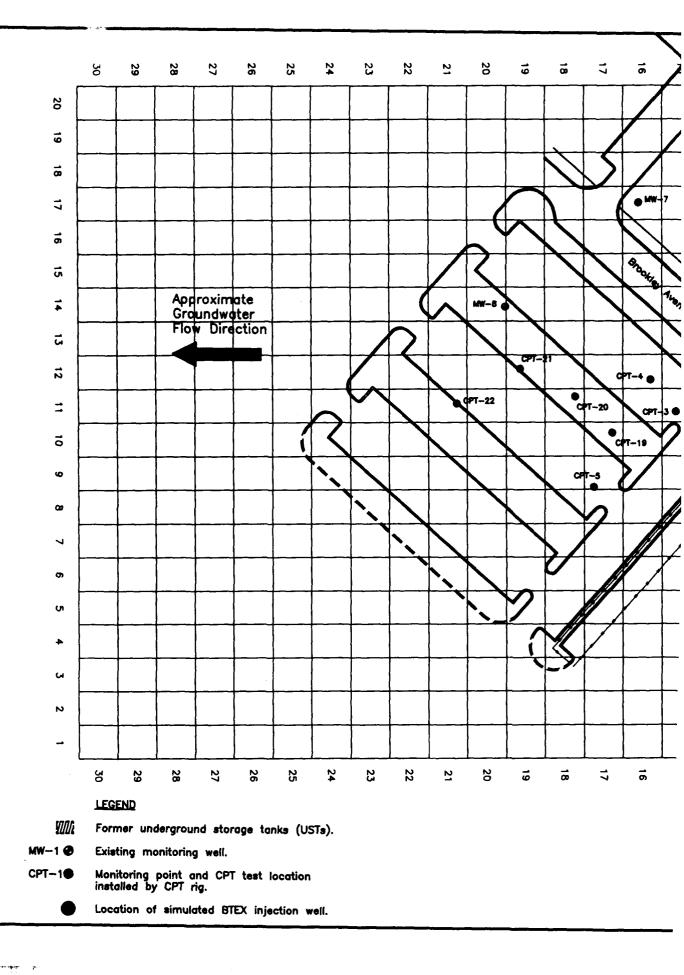

Model boundaries are mathematical statements that represent hydrogeologic boundaries, such as areas of specified head (e.g., surface water bodies or contour lines of constant hydraulic head) or specified flux. Hydrogeologic boundaries are represented by three mathematical statements that describe the hydraulic head at the model boundaries. These include:

1) Specified-head boundaries (Dirichlet condition) for which the head is determined as a function of location and time only. Surface water bodies exhibit constant head conditions. Specified-head boundaries are expressed mathematically as:

$$Head = f(x, y, z, t)$$

where f is the function symbol, x, y, and z are position coordinates, and t is time.

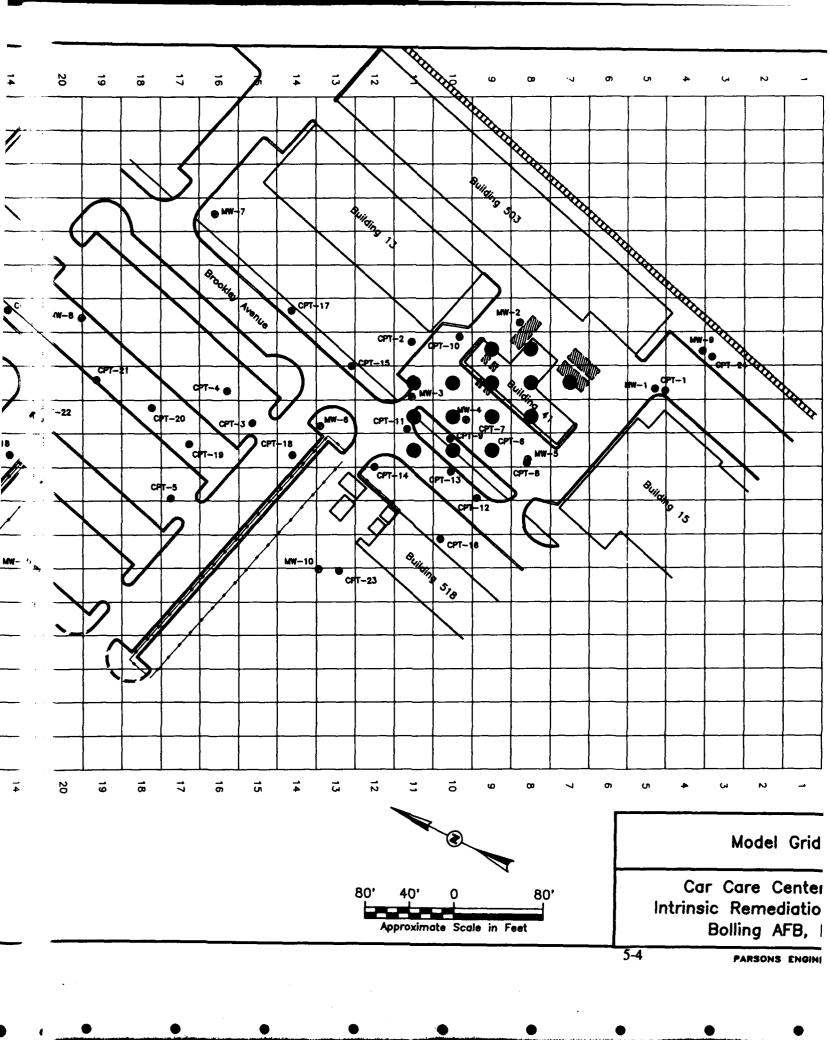

2) Specified-flow boundaries (Neumann conditions) for which the mathematical description of the flux across the boundary is given. The flux is defined as a volumetric flow rate per unit area (e.g., ft³/ft²/day). No-flow boundaries are a

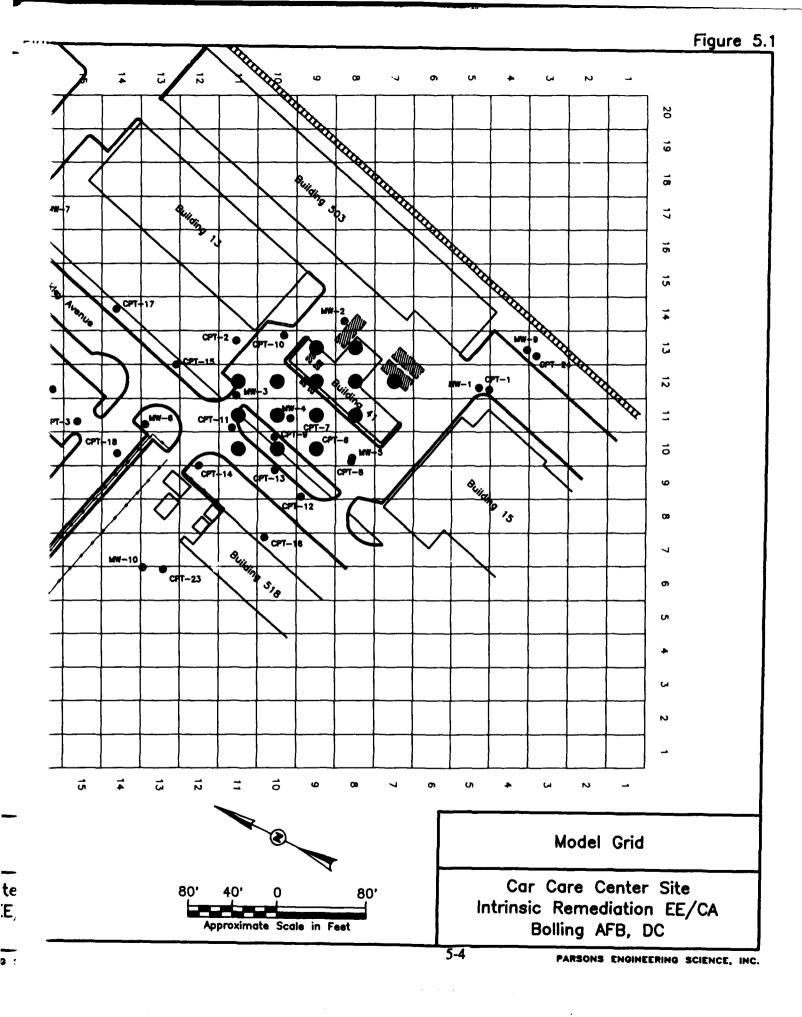

1 / 1-25-95 / TLP

2245051 dwo

1

special type of specified flow boundary and are set by specifying the flux to be zero. Examples of no-flow boundaries include groundwater divides and impermeable hydrostratigraphic units. Specified-flux boundaries are expressed mathematically as:

Flux = f(x, y, z, t)

3) Head-dependent flow boundaries (Cauchy or mixed-boundary conditions) where the flux across the boundary is calculated from a given boundary head value. This type of flow boundary is sometimes referred to as a mixed-boundary condition because it is a combination of a specified-head boundary and a specified-flow boundary. Head-dependent flow boundaries are used to model leakage across semipermeable boundaries. Head-dependent flow boundaries are expressed mathematically as (Bear, 1979):

Flux=(Ho - H)K'/B'

Where:

H = Head in the zone being modeled (generally the zone

containing the contaminant plume)

Ho ≈ Head in external zone (separated from plume by semipermeable layer)

K' = Hydraulic conductivity of semipermeable layer

B' = Thickness of semipermeable layer.

Natural hydraulic boundaries are modeled using a combination of the three types of model boundary conditions listed above. When possible, hydrologic boundaries such as surface water bodies, groundwater divides, contour lines, or hydrologic barriers should coincide with the perimeter of the model. In areas lacking obvious hydrologic boundaries, specified-head or specified-flux boundaries can be specified at the model perimeter if the boundaries are far enough removed from the contaminant plume that transport calculations are not affected. Bioplume II requires the entire model domain to be bounded by zero-flux cells (also known as no-flow cells), with other boundary conditions established within the subdomain specified by the no-flow cells.

Specified-head boundaries for the model were set on the southeastern and northwestern perimeter of the model grid to simulate groundwater flow to the northwest as observed at the site. Heads for the specified-head boundaries were set at the approximate location of the water table indicated by water level data. The head of the southeastern boundary (upgradient) was estimated to be from 4.25 to 14.75 feet above msl in order to simulate the steep gradients observed at the upgradient boundary. However, plume formation and transport only occur in the portion of the model domain where the water table surface is relatively flat. As a result, mass transport in the plume is not affected by the boundary conditions used to reproduce the observed water table conditions.

Parsons ES chose not to utilize the Potomac River as the model downgradient boundary due to its excessive distance from the site. An alternate model boundary was chosen in order to maintain resolution of the BTEX plume and to avoid potential

boundary interferences. As a result, downgradient model boundary was defined by an assumed downgradient position of the 2.0-foot water table contour. The location of this contour was estimated by extrapolation from available water table elevation and flow gradient data.

The southwestern and northeastern (lateral) model boundaries were configured as no-flow (specified flux) boundaries. Flux through these boundaries is assumed to be zero because flow is generally parallel to these boundaries.

5.3.2 Groundwater Elevation and Gradient

The water table elevation map presented in Figure 3.5 was used to define the starting heads for input into the Bioplume II model. Groundwater flow in the vicinity of the former Car Care Center Site (Building 41) is to the south with an average gradient of approximately 0.014 foot/foot (see Section 3.3.2.1). A comparison of the hydraulic gradients calculated by Parsons ES and Baker (1994) suggest that there are no significant seasonal variations in groundwater flow direction, and that seasonal gradients consistently vary around the average of approximately 0.014 foot/foot. As a result, it was assumed that the observed water levels were representative of steady-state conditions. As described in Section 5.4.1, the model was calibrated to the observed water table.

5.3.3 BTEX Concentrations

August 1994 total dissolved BTEX concentrations obtained from laboratory analytical results for each well and monitoring point location were used for model development. At each multidepth monitoring point, the highest BTEX concentration observed at that location was used as the representative concentration. Table 4.2 presents dissolved BTEX concentration data. Figure 4.4 shows the spatial distribution of dissolved BTEX compounds in August 1994.

The BTEX plume observed in August 1994 covers an area of approximately 126,000 square feet (2.9 acres). The shape and distribution of the total BTEX plume is the result of advective-dispersive transport, sorption, and biodegradation of dissolved BTEX contamination. As described in Section 5.4.2, the simulated BTEX plume was calibrated to closely approximate the observed BTEX plume.

5.3.4 Electron Acceptors (Oxygen and Nitrate)

As discussed previously, the Bioplume II model assumes an instantaneous reaction between the BTEX plume and the DO plume. The discussion presented in Section 4 suggests that DO, nitrate, ferric iron, manganese, sulfate, and carbon dioxide are being used as electron acceptors for biodegradation of BTEX compounds at the former Car Care Center Site (Building 41). To be conservative, the total BTEX plume at the site was modeled assuming that DO and nitrate were the only electron acceptors being utilized for the biodegradation of BTEX compounds at a rate that is instantaneous relative to the advective groundwater flow velocity.

Groundwater samples collected, during August 1994, in uncontaminated portions of the aquifer suggest that the background DO concentration at the site was 5.2 mg/L.

Background oxygen levels were assumed to be 5 mg/L for Bioplume II model development. Table 4.3 presents DO data for the site. Figure 4.8 presents the August 1994 DO isopleth map, and Figures 4.9 and 4.10 show the vertical profiles. Gridded oxygen input data are included in Appendix D. Nitrate and nitrite concentrations in groundwater were determined from site monitoring wells and monitoring points. Groundwater samples collected from uncontaminated portions of the aquifer suggest that background nitrate concentrations ranged from 13 to 18 mg/L (as nitrogen). However, due to spatial position of the August 1994 nitrate plume (Figure 4.11), the 5.0 mg/L (as nitrogen) contour was the largest significant isopleth. Therefore, background nitrate levels were assumed to be 5 mg/L (as nitrogen) for Bioplume II model development. Table 4.3 presents nitrate data for the site. Figure 4.8 presents nitrate isopleth map for August 1994.

The upgradient specified-head cells in the Bioplume II model require background DO (or electron acceptors) to be input as a single constant concentration at each upgradient boundary cell. As a result, nitrate concentration must be converted to an oxygen equivalent. As a first step, the equivalent weight of oxygen must be added to the nitrate, expressed as N, to convert to ionic nitrate:

Molecular weight of N = 14 gm/mole Molecular weight of O = 16 gm/mole Molecular weight of NO₃ = 62 gm/mole

The percentage of N in NO_3 is 14/62 = 22.58 percent. Therefore, 1 gm of NO_3 (as N) is equivalent to 1/0.2258 = 4.43 gm of ionic NO_3 . To convert nitrate (as N) into ionic nitrate concentrations, the measured nitrate (as N) concentration must be multiplied by 4.43.

Assuming complete mineralization of benzene to carbon dioxide and water, the reactions for aerobic respiration and denitrification are as follows:

Aerobic Respiration

$$C_6H_6 + 7.5O_2 = 6CO_2 + 3H_2O$$

Denitrification
$$6NO_3^- + 6H^+ + C_6H_6 = 6CO_2 + 6H_2O + 3N_{2(g)}$$

Based on this stoichiometry, 7.5 moles of DO are required to biodegrade 1 mole of benzene, and 6 moles of nitrate are required to biodegrade 1 mole of benzene. On a mass basis:

$$(7.5 \text{ moles O}_2)(32 \text{ gm/mole O}_2) = 240 \text{ gm O}_2$$

(6 moles NO₃')(62 gm/mole NO₃')= 372 gm NO₃'

From these relationships, it is apparent that on a mass basis more ionic nitrate than DO is required to oxidize a unit mass of benzene. By dividing the mass of ionic nitrate required to degrade one mole of benzene by the mass of DO required to degrade one mole of benzene, a ratio is derived that can be applied to ionic nitrate concentrations to obtain equivalent oxygen concentrations. This ratio is:

240 gm $O_2/372$ gm $NO_3^- = 0.645$ gm of O_2 -equivalent ionic nitrate per/gram of NO_3^-

Therefore, 10 gm of NO₃ has an O₂ equivalence of:

(10 gm NO_3)(0.645 gm of O_2 -equivalent ionic nitrate per gm of NO_3) = 6.45 gm

From these relationships, the following calculation must be performed to convert NO₃ (as N) to an equivalent DO concentration:

(NO₃ (as N) (gm/L))(4.43 gm NO₃ (ion)/gm NO₃ (as N))(0.65 gm O₂ eq./gm NO₃)

This relationship was used to convert measured nitrate (as N) concentrations into oxygen-equivalent ionic nitrate concentrations. For example, the 5 mg/L (as nitrogen) background nitrate concentration is converted to 14.5 mg/L (as O_2 equivalent). To do this, an isopleth map of nitrate (as N) was prepared and gridded. An O_2 equivalent of 19.5 mg/L was assumed for the starting condition at all model cells prior to the introduction of fuel contamination. It was further assumed that this concentration would be continually introduced at the upgradient boundary.

5.3.5 Anaerobic Degradation Rates

In order to calculate first-order decay rate constants in the anaerobic core of the plume, the apparent degradation rate must be normalized for the effects of dilution caused by advective-dispersive processes. This is accomplished by normalizing the concentration of each contaminant to the concentration of a component of gasoline (a tracer) that has similar sorptive properties but that is fairly recalcitrant. Observed concentration data can be normalized to 1,3,5-TMB, 1,2,4-TMB, and 1,2,3-TMB or another tracer with similar physiochemical properties. The TMB suite serves as a good tracer because it is known to be recalcitrant to microbial degradation under anaerobic conditions, and has sorptive properties similar to the BTEX compounds.

First-order decay constants were calculated based on BTEX and TMB data from August 1994 (presented in Table 4.2). Rate constant calculations are included in Appendix D. Calculated rate constants for the Car Care Center Site (Building 41) ranged from 0.0001 to 0.0004 day⁻¹. A review of recent literature indicates that higher rate constants have been observed at other sites. For example, Chapelle (1994) reported that at two different sites with anaerobic conditions, the anaerobic rate constants were both approximately 0.01 day⁻¹. Wilson et al. (1994) report first-order anaerobic biodegradation rates of 0.05 to 1.3 week⁻¹ (0.007 to 0.185 day⁻¹). Stauffer et al. (1994) reports rate constants of 0.01 day⁻¹ and 0.018 day⁻¹ for benzene and p-xylene, respectively. The calculated first-order decay rate for this site is relatively low. A major controlling factor for the rate of biodegradation is the quantity of electron acceptors that are flushed from upgradient areas through the contaminated zone. This low decay coefficient is likely a result of the minimal groundwater flow rate reported at the site.

Because nitrate was included in the Bioplume II model, and to be conservative, first-order decay was not included within the model.

5.4 MODEL CALIBRATION

Model calibration is an important component in the development of any numerical groundwater model. Calibration of the flow model demonstrates that the model is capable of matching hydraulic conditions observed at the site. Calibration of a contaminant transport model superimposed upon the calibrated flow model helps verify that contaminant loading and transport conditions are being appropriately simulated. The numerical flow model presented herein was calibrated by altering transmissivity in a trial-and-error fashion until simulated heads approximated observed field values within a prescribed accuracy. After calibration of the flow model, the numerical transport model was calibrated by altering transport parameters in a trial-and-error fashion until the simulated BTEX plume approximated observed field values. Table 5.1 lists input parameters used for the modeling effort. Model input and output is included in Appendix D.

5.4.1 Water Table Calibration

The shallow water table at the former Car Care Center Site was assumed to be influenced only by continuous recharge and discharge at the constant-head cells established at the upgradient and downgradient model boundaries. To be conservative, recharge of the aquifer through rainfall (which would add water, thereby increasing dilution of the plume) was not included in the model. Potential recharge by other sources was omitted because of a lack of reliable data. Only the initial water levels at the constant-head cells and the transmissivity values were varied to calibrate the water table surface. The model was calibrated under steady-state conditions.

Hydraulic conductivity is an important aquifer characteristic that determines the ability of the water-bearing strata to transmit groundwater. Transmissivity is the product of the hydraulic conductivity and the thickness of the aquifer. An accurate estimate of hydraulic conductivity is important to help quantify advective groundwater flow velocities and to define the flushing potential of the aquifer and the quantity of electron-acceptor-charged groundwater that is entering the site from upgradient locations. As indicated by the work of Rifai et al. (1988), the Bioplume II model is particularly sensitive to variations in hydraulic conductivity. Lower values of hydraulic conductivity result in a slower-moving plume that degrades at a slower rate because less oxygen, nitrate, iron, sulfate, and carbon dioxide is available for biodegradation. Higher values of hydraulic conductivity result in a faster-moving plume that degrades faster because more electron acceptors are available for biodegradation.

Saturated thickness data from previous reports, geologic logs, and water level measurements were used in conjunction with the average hydraulic conductivity as determined from slug tests performed by Baker in 1994 (5.8 x 10⁻⁵ feet/sec to 5.8 x 10⁻⁶ feet/sec) to estimate an initial uniform transmissivity for the entire model domain. Several pre-calibration model runs were made to determine if model input parameters were appropriate. The simulations were run for 50 years (the approximate operational lifetime of the Car Care Center) to determine if the initial parameters would

produce reasonable simulations, and to provide a preliminary estimate of BTEX injection rates (see Section 5.4.2 for additional information on BTEX injection). During these simulations, it became apparent that the use of the original hydraulic conductivity values estimated from site data prevented reproduction of the observed site conditions. BTEX plumes simulated in these initial runs were all less than one-third the length of the observed plume. Varying transport parameters such as the retardation factor, the reaeration coefficient, and the longitudinal dispersivity within reasonable ranges did not increase the plume length substantially. As a result, model hydraulic conductivities were increased until the observed plume length was adequately reproduced. The resulting average model conductivity (and hence transmissivity) value was 4.8 times greater than that reported by Baker (1994). The resulting transmissivity of 0.0051 feet²/sec was used for initial model setup. Because slug test data at best provide a measurement of conductivity within an order-of-magnitude, this change is not excessive. Model sensitivity to transmissivity (hydraulic conductivity times saturated thickness) is discussed in Section 5.5.

To better match heads in the model to observed values, the transmissivities were then progressively varied in blocks and rows until the simulated water levels for cells corresponding to selected well locations matched the observed water levels as closely as possible. Figure 5.2 shows the calibrated water table. Calibrated model hydraulic conductivities ranged from 1.7 x 10⁻⁴ feet/sec to 3.4 x 10⁻⁶ feet/sec. Water level elevation data from cells associated with 10 monitoring wells and monitoring points were used to compare measured and simulated heads for calibration. The 10 selected cell locations each contained one of the following wells: MW-1, MW-3, MW-4, MW-5, MW-6, MW-7, MW-8, MW-9, CPT-8D, and CPT-22D. The root mean squared (RMS) error is commonly used to express the average difference between simulated and measured heads. RMS error is the average of the squared differences between measured and simulated heads, and can be expressed as:

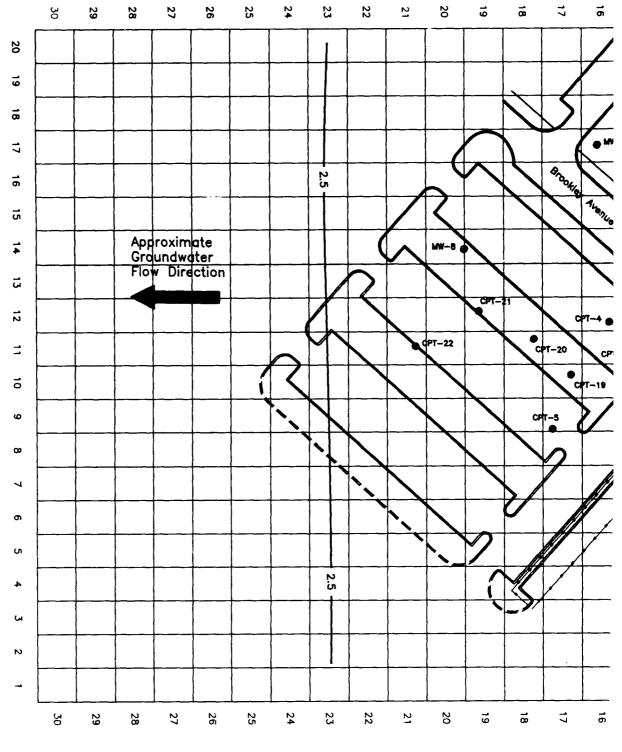

RMS :=
$$\left[\frac{1}{n} \cdot \sum_{i=1}^{n} \left[\left(h_{m} - h_{s}\right)_{i}\right]^{2} \right]^{0.5}$$

n = the number of points where heads are being compared Where:

 h_m = measured head value

h, = simulated head value.

The RMS error between observed and calibrated values at the 10 comparison points was 0.30 feet, which corresponds to a calibration error of 2.4 percent (water levels dropped a maximum of 12.6 feet over the length of the model grid). RMS error calculations are summarized in Appendix D. A plot of measured vs. calibrated heads shows a random distribution of points around a straight line, as shown in Appendix D. Deviation of points from a straight line should be randomly distributed in such a plot of results from computer simulations (Anderson and Woessner, 1992).

The coefficient of correlation (R²) is a measure of the similarity between two data sets. In the event that R² is equivalent to 1, then the data are a perfect match. The R² for this plot was 0.65, indicating that the difference between the simulated and observed heads is not exact. This low R² value is partially due to the steep gradients observed along the upgradient site boundary, which were difficult to model accurately. Also, the site monitoring wells typically do not fall within the center of a model grid. Because the Bioplume II model provides block-centered data, the simulated and observed heads typically will not be exact. The slope and intercept of the regression curve is another indication of exactness between the simulated and observed heads. If the data is a good match, the slope and y-intercept of the regression line should be 1.0 ft/ft and 0.0 foot, respectively. For this data, the slope of the regression line was 0.95 ft/ft and the y-intercept was 0.0 foot, indicating a satisfactory match between the simulated and observed heads.

In solving the groundwater flow equation, Bioplume II establishes the water table surface and calculates an overall hydraulic balance that accounts for the numerical difference between flux into and out of the system. The hydraulic mass balance for the calibrated model was excellent, with 99.8 percent of the water flux into and out of the system being numerically accounted for (i.e., a 0.2 percent error). According to Anderson and Woessner (1992), a mass balance error of around 1 percent is acceptable, while Konikow (1978) indicates an error of less than 0.1 percent is ideal.

5.4.2 BTEX Plume Calibration

Model input parameters affecting the distribution and concentration of the simulated BTEX plume were modified so that model predictions matched dissolved total BTEX concentrations observed in August 1994. To do this, model runs were made using the calibrated steady-state hydraulic parameters coupled with the introduction of contaminants. For this site, the calibration also involved a time element. The exact dates and volumes of the releases are unknown because the historical record for these events is not complete. Leaks from the USTs and piping may have occurred gradually over a long period of time. However, spills likely occurred as early as 20 to thirty years ago. As a result, the plume calibration simulations were made with a time constraint of 20 years; in other words, computed BTEX plume concentrations and configurations were compared to August 1994 data after 20 years of simulation time incorporating the introduction of contaminants into the groundwater.

Because mobile and residual LNAPL are present in the vicinity of the water table at the site, it was necessary to include model injection wells to simulate partitioning of BTEX compounds from the residual phase into the groundwater. The location of the injection wells is shown on Figure 5.1. Locations of injection wells were based on the known locations of mobile and residual LNAPL (see Figure 4.1, 4.2a, and 4.2b), the extent of groundwater contamination indicated on Figure 4.4, and the locations of the USTs and fuel piping.

While the term "injection well" suggests contaminants are being introduced at a point, Bioplume II assumes that contamination introduced at a well instantly equilibrates throughout the entire cell in which the well is located. The injection rate for the cells was set at 4.6×10^{-6} cubic foot per second (ft³/sec), a value low enough so that the flow calibration and water balance was not affected. Relatively high BTEX

concentrations were injected in upgradient injection wells because of the low pumping rate and the influx of oxygen introduced at the upgradient constant head cells. Replenishment of oxygen quickly degraded BTEX concentrations at the head of the plume, which in turn required larger injection concentrations of BTEX to produce observed BTEX contours. Based on assumptions outlined in Section 5.3.4, it was assumed that the initial DO concentration was uniformly 5.0 mg/L and initial nitrate concentration was uniformly 5.0 mg/l (as nitrogen), and that water with these concentrations would be continually introduced at the upgradient boundary.

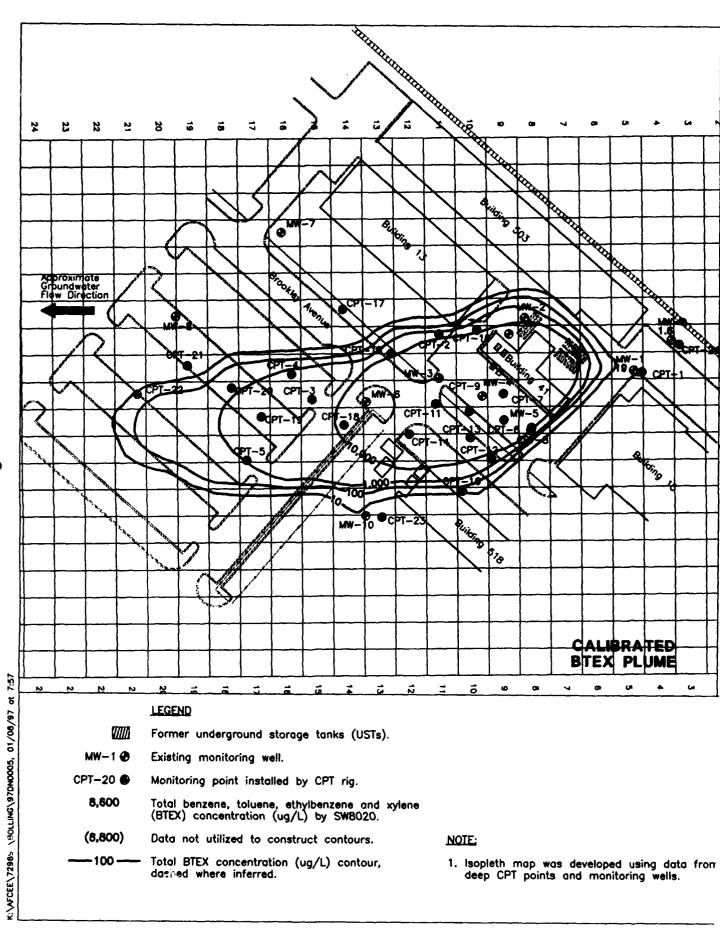

Total BTEX injection concentrations were determined by varying the injection concentration for the various wells until the modeled total BTEX plume approximated the total BTEX plume observed in August 1994. By varying the injection well concentrations, the coefficient of retardation, dispersivity, and the reaeration coefficient, the BTEX plume was calibrated reasonably well to the existing plume in terms of migration distance and BTEX concentrations in the source area. The calibrated plume configuration is shown and compared to the August 1994 observed BTEX plume on Figure 5.3.

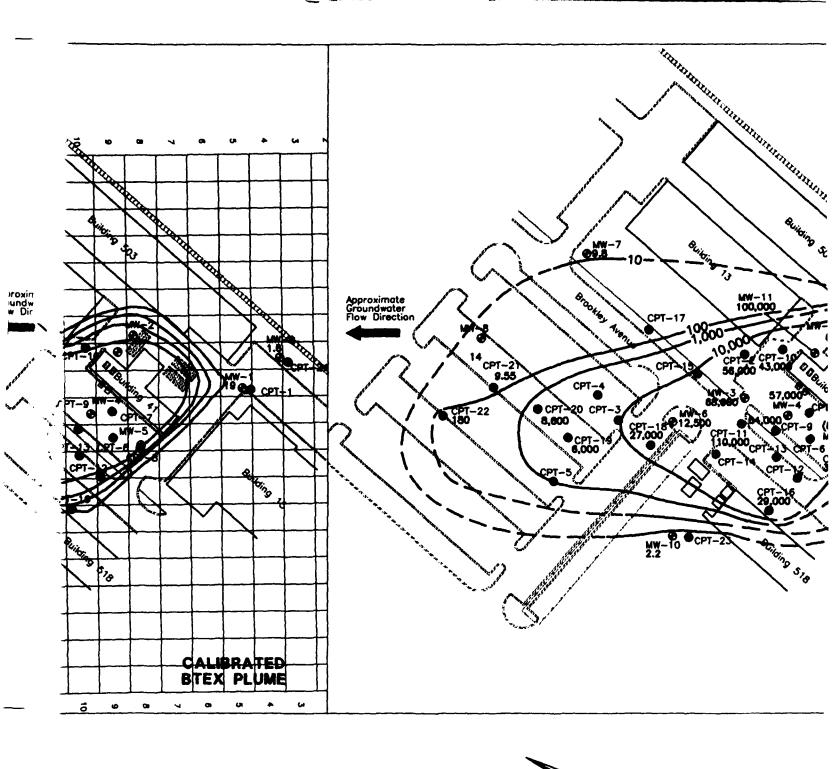

The calibrated model plume, while not identical to the observed BTEX plume, compares favorably. Differences in modeled and actual plume shapes and concentrations are caused by physical, chemical, and biological variations within the shallow saturated zone that result from natural aquifer heterogeneity. The downgradient extent of the computed 10 $\mu g/L$ contour is similar to the observed 10 $\mu g/L$ contour, and the computed 100 $\mu g/L$ BTEX contour is similar to the 100 $\mu g/L$ contour interpreted from the observed concentrations. The area delineated by the computed 1,000 $\mu g/L$ contour is slightly smaller than the area of the observed 1,000 $\mu g/L$ contour along the western edge of the plume. However, these differences are relatively minor. In addition, the downgradient extent of the computed 10,000 $\mu g/L$ BTEX contour is similar to the observed 10,000 $\mu g/L$ contour's extent.

The computed plume does not have concentrations as high as the concentration observed at CPT-11S (110,000 $\mu g/L$), with a maximum simulated concentration of 30,200 $\mu g/L$ computed for the cell containing CPT-11S. However, the measurement at CPT-11S was made at a discrete interval within the aquifer, while the model is indicating a concentration that is averaged for the entire model cell depth. Measured BTEX concentrations in CPT-11D were 3,100 $\mu g/L$, which further emphasizes the effect of vertical averaging within the model. Increasing the BTEX loading rates high enough to produce concentrations over 50,000 $\mu g/L$ in the source ea resulted in a plume that was much longer and wider than the observed plume.

5.4.2.1 Discussion of Parameters Varied During Plume Calibration

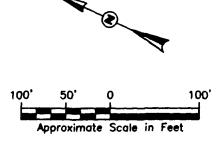

As noted previously, the transport parameters varied during plume calibration were dispersivity, the coefficient of retardation, and the reaeration coefficient. Those parameters were generally varied with the intent of altering plume migration so that the observed plume extent was reproduced. While these parameters were varied with this common intent, each had a slightly different impact on the size and shape of the simulated plume.

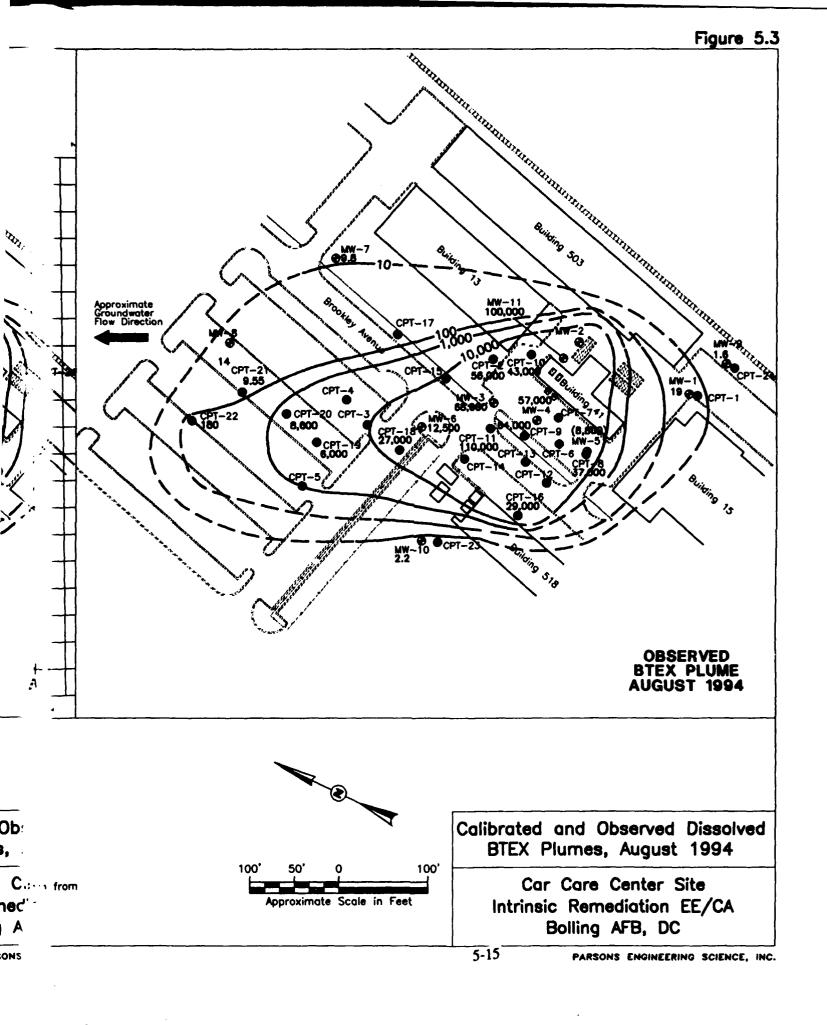

NOTE:

5 4.2.1.1 Dispersivity

Much controversy surrounds the concepts of dispersion and dispersivity. Longitudinal dispersivity values are typically considered to be scale dependent. In other words, for a given sediment type, dispersivity values will depend upon the distance traveled by the solute. Gelhar et al. (1985) performed a critical review of various field experiments and found the longitudinal dispersivities varied from 0.03 feet to 18,000 feet. It may be inferred from this report that longitudinal dispersivity may range from 5 to 200 feet for the plume length reported for the former Car Care Center Site. Longitudinal dispersivity was originally estimated as 15 feet, using one-tenth (0.1) of the distance between center of the source area and the longitudinal centroid of the August 1994 plume (see Figure 4.4). Dispersivity estimation calculations are included in Appendix D. Transverse dispersivity values generally are estimated as one-tenth (0.1) of the longitudinal dispersivity values (Domenico and Schwartz, 1990).

During plume calibration, longitudinal dispersivity was raised to 25 feet from the original estimate of 15 feet. This was done to allow the computed BTEX plume to extend slightly further downgradient and also to help increase the lateral extent of the plume to better match the observed extent.

5.4.2.1.2 Coefficient of Retardation

Retardation of the BTEX compounds relative to the advective velocity of the groundwater occurs when BTEX molecules are sorbed to the aquifer matrix. The coefficients of retardation for the BTEX compounds were calculated based on measured TOC concentrations in the soils in and near the saturated zone at the site, an assumed bulk density of 1.6 grams/cubic centimeter (Freeze and Cherry, 1979), and published values of the soil sorption coefficient (K_{∞}) for the BTEX compounds, as listed by Wiedemeier et al. (1994). The results of these calculations are summarized in Table 5.2. To be conservative, the minimum retardation coefficient calculated for the BTEX compounds (R=1.25) was used for initial model input. The lower the assumed coefficient of retardation, the farther the BTEX plume will migrate downgradient. During plume calibration, the coefficient of retardation was gradually raised from the initial value of 1.25 to a value of 4.2 and also decreased to a value of 1. This analysis suggests that the initial retardation coefficient (R=1.25) adequately describes the formation of the present-day BTEX plume. As a result, this value was used in the final model simulations.

5 4.2.1.3 Reaeration Coefficient

The reaeration coefficient is a first-order rate constant used by Bioplume II to simulate the replenishment of oxygen into the groundwater by soil-gas diffusion and rainwater infiltration. A reaeration coefficient of 0.003 day⁻¹ was initially estimated, based on other documented Bioplume II modeling efforts (see, for example, Rifai et al., 1988). Use of the reaeration coefficient is justified at this site because of the shallow water table and the relatively high DO concentrations observed in site groundwater. During plume calibration, the reaeration coefficient was varied from the initial value of 0.003 day⁻¹ to values of 0.03 day⁻¹ and 0.0003 day⁻¹. This analysis suggested that the initial retardation coefficient (0.003 day⁻¹) adequately describes the

5.5 SENSITIVITY ANALYSIS

The purpose of the sensitivity analysis is to determine the effect of varying model input parameters on model output. Based on the work of Rifai et al. (1988), the Bioplume II model is most sensitive to changes in the coefficient of reaeration, the coefficient of anaerobic decay, and the hydraulic conductivity of the media, and is less sensitive to changes in the retardation factor, porosity, and dispersivity. A first-order anaerobic decay coefficient was not used because nitrate was included in the original oxygen map to simulate anaerobic biodegradation at the site. Because the coefficient of anaerobic decay was set to zero, the sensitivity analysis was conducted by varying the hydraulic conductivity (and therefore transmissivity) and the coefficient of reaeration. Because of the potential for large dispersivity values at the site, a sensitivity analysis also was performed for this parameter. In addition, a sensitivity analysis was performed for the retardation coefficient.

To perform the sensitivity analyses, individual runs of the model were made with the same input as the calibrated model, except that one of the aforementioned parameters was varied. The models were run for 20 years, just as the calibrated model, so that the independent effect of each variable could be assessed. As a result, eight sensitivity runs of the calibrated model were made, with the following variations:

- 1) Hydraulic conductivity uniformly increased by a factor of 5;
- 2) Hydraulic conductivity uniformly decreased by a factor of 0.2;
- 3) Longitudinal dispersivity increased to 50 feet;
- 4) Longitudinal dispersivity decreased to 5 feet;
- 5) Reaeration coefficient increased to 0.03 day⁻¹;
- 6) Reaeration coefficient decreased to 0.0003 day⁻¹;
- 7) Retardation coefficient increased to 4.2; and
- 8) Retardation coefficient decreased to 1 (i.e. no retardation).

The results of the sensitivity analyses are shown graphically in Figures 5.4, 5.5, 5.6, and 5.7. These figures display the modeled BTEX concentrations versus distance along the centerline of the plume. This manner of displaying data is useful because the plume is narrow and migrates parallel to the model grid. Furthermore, the figures allow easy visualization of the changes in BTEX concentration caused by varying model input parameters.

•

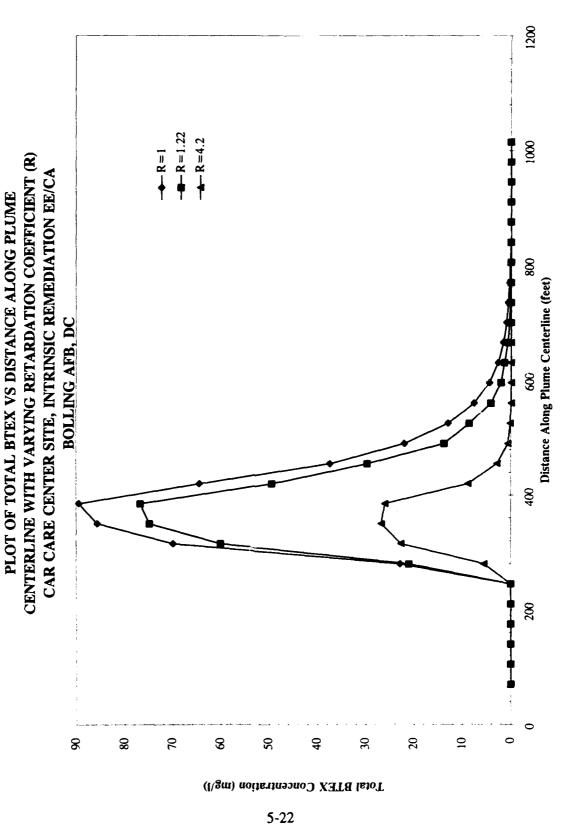

FIGURE 5.7

Uniformly increasing the hydraulic conductivity in the model by a factor of 5 drastically increased the migration rate and biodegradation rate of the plume (Figure 5.4). In relation to the calibrated plume, the plume formed by the model with the higher hydraulic conductivity had a lower peak (due to increased biodegradation) and was spread much further downgradient (due to increased advective flow). This was caused by an increased influx of electron acceptors in the highly conductive aquifer, increasing biodegradation of the plume in the source area. Also, the higher groundwater velocity produced greater downgradient spreading of the BTEX plume. In contrast, decreasing the hydraulic conductivity by a factor of 0.2 slowed plume migration, which in turn caused an increase in modeled BTEX levels in the source area and a decreased downgradient plume extent. Increased BTEX concentrations in the source area are caused by a reduction in the quantity of electron acceptors being brought into contact with the plume from upgradient locations.

The effect of varying the coefficient of reaeration is shown in Figure 5.5. Increasing the reaeration coefficient from 0.003 day⁻¹ to 0.03 day⁻¹ significantly decreased BTEX concentrations and restricted plume migration. By reducing the reaeration coefficient by an order of magnitude (to 0.0003 day⁻¹), the length of the modeled BTEX plume increased greatly, as did the maximum concentration. The downgradient end of the plume extended approximately 600 feet past its observed location.

Figure 5.6 illustrates the effects of varying longitudinal dispersivity. This model is relatively insensitive to dispersivity. Decreasing the dispersivity reduced the migration distance for the BTEX plume and slightly increased peak concentrations. Lowering dispersivity keeps the plume from spreading out into more electron acceptor-rich portions of the aquifer. Conversely, increasing dispersivity produced slightly lower BTEX concentrations in the source area and increased the plume migration distance.

Figure 5.7 shows the sensitivity of the model to the coefficient of retardation. The coefficient of retardation was decreased from the calibrated value of 1.22 to 1, which results in no retardation. Removing retardation from the model slightly increased the maximum BTEX concentrations and the downgradient plume migration distance. Increasing the coefficient of retardation to 4.2 significantly decreased the peak plume concentrations and limited the migration of the plume.

The results of the sensitivity analysis suggest that the calibrated model used for this report is reasonable. Changing the coefficient of reaeration, hydraulic conductivity, or the coefficient of retardation can significantly affect the predicted BTEX concentrations and distribution so that conditions observed in August 1994 are not reasonably reproduced.

5.6 Model Results

The Bioplume II model was run under steady-state conditions with no contamirant source removal (model CAL2), 20-percent annual source removal (model SR20), and 33-percent annual source removal (model SR33) until the plume reached steady-state equilibrium (no source removal) or until the plume disappeared (source removal scenarios). As previously mentioned, continuing sources of groundwater contamination at the site exist mainly in the form of soil contamination and residual LNAPL

contamination. Only, minimal mobile LNAPL thicknesses were observed within site monitoring wells. Contaminant source reduction in concert with natural attenuation can significantly reduce the longevity of the dissolved BTEX contamination at the site.

Although the results of each model run varied depending on the amount of source injection concentration over time, two trends were consistently observed:

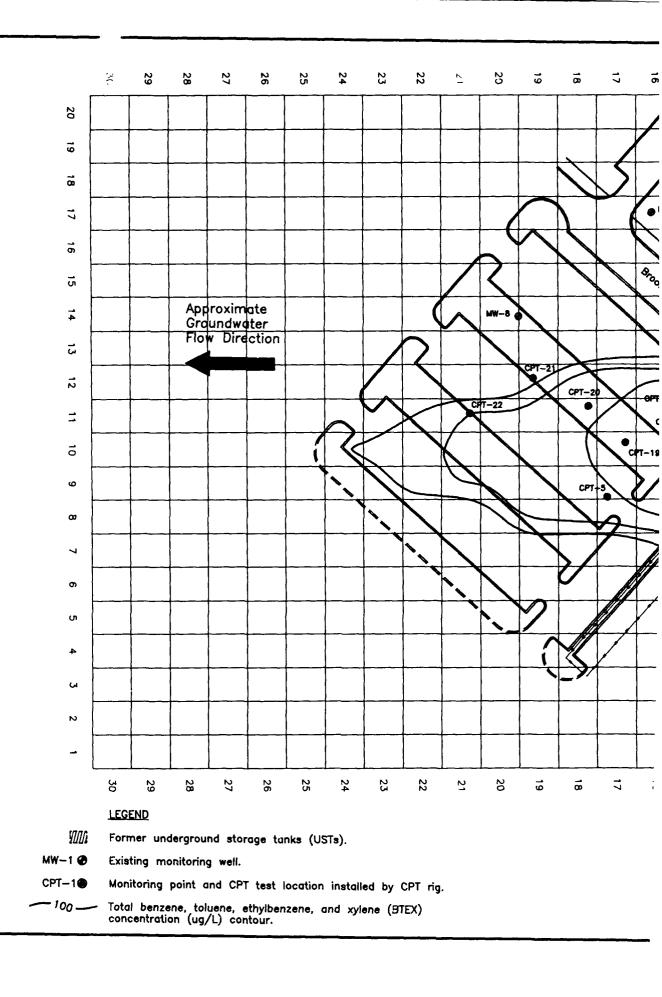

- 1) The plume shape in each simulation is elongated due to rapid advective transport of BTEX contamination and rapid biodegradation of BTEX at the plume periphery;
- 2) Model SR20 required 5 years to accomplish source removal whereas model SR33 required 3 years to accomplish source removal. When plume migration is compared starting from the time of source removal completion, there are minimal differences between the models. The hydrocarbon plume disappears approximately 10 years are source is completely removed for both scenarios. This occurs are replenished electron acceptor concentrations eventually exceed the dissolved BTEX concentrations introduced into the aquifer by a ratio greater than 3.1:1

The following sections describe the results of each model scenario.

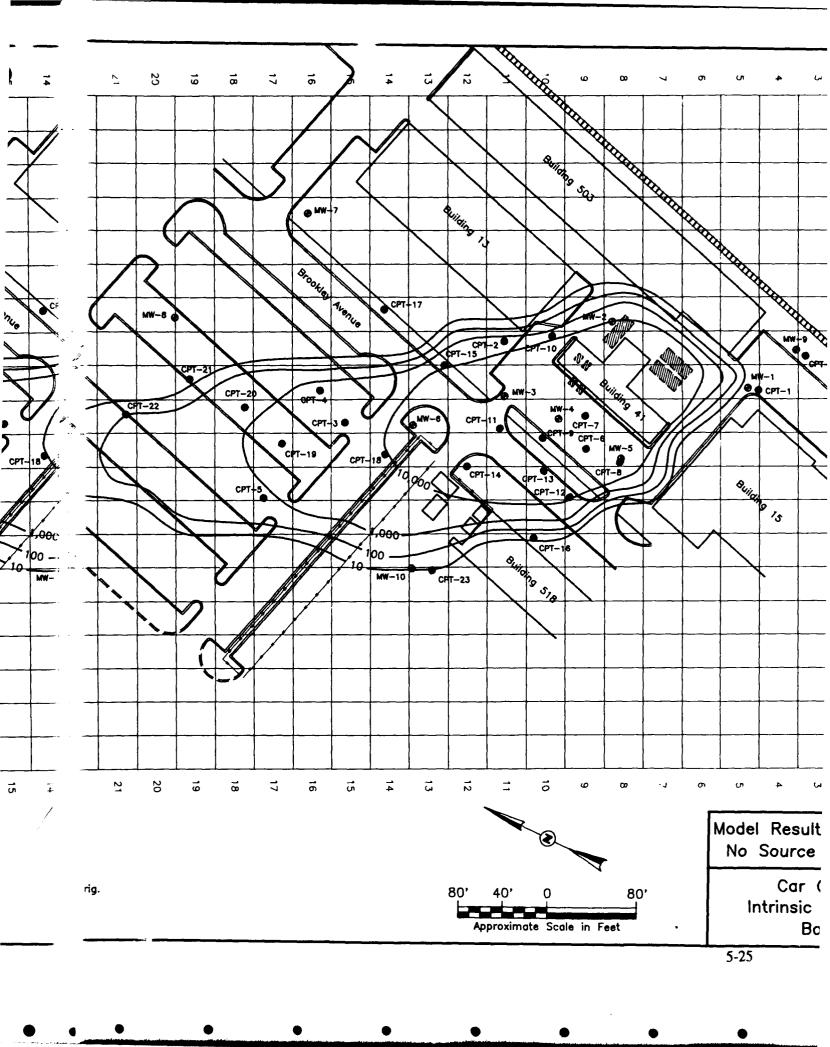

5.6.1 No Source Removal (Model CAL2)

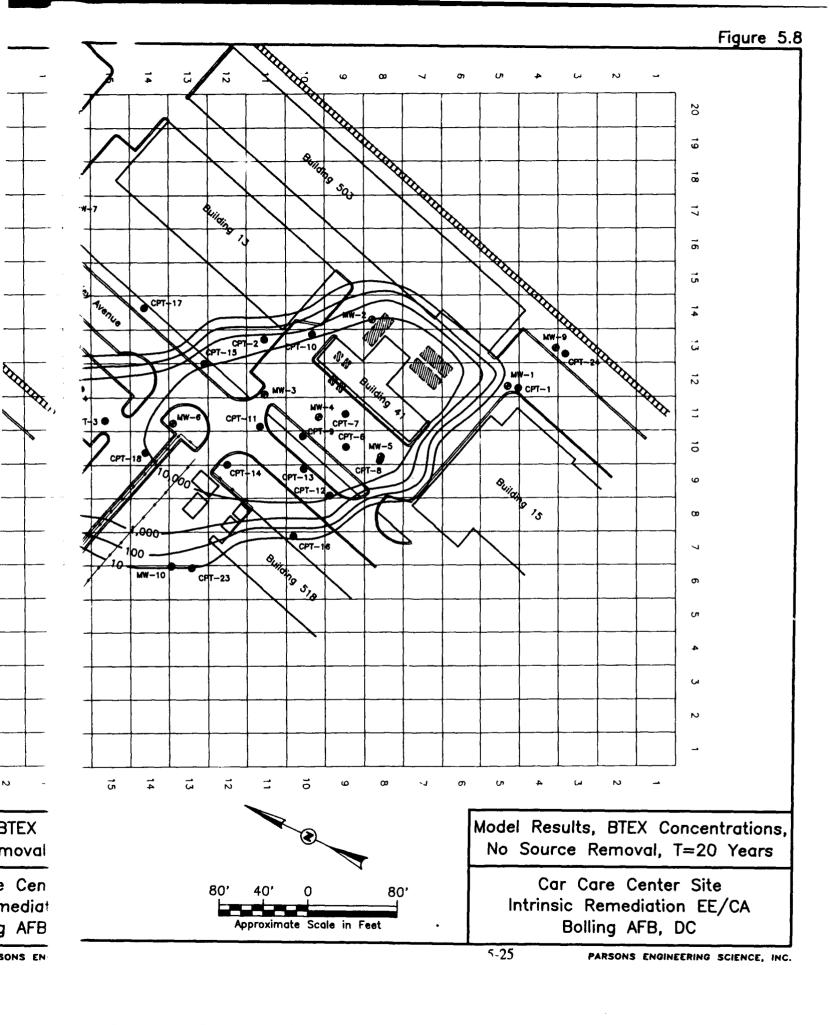

Model CAL2 simulated the migration and biodegradation of the BTEX plume assuming no source weathering or removal. First-order decay was not included within the model. This model assumed that the conditions that produced the calibrated model continued, including injection of BTEX compounds at the same rates. This simulation was run to predict conditions up to 30 years beyond the calibrated model end time, or 30 years past 1994. Contaminant migration within the simulation was relatively slow because of the moderate hydraulic conductivity and shallow hydraulic gradient at the site. The Bioplume II model predicted that the plume would reach steady-state equilibrium within approximately 30 years. Figures 5.8 and 5.9 show the predicted total BTEX concentrations at years 20 and 30. The plume migrates in the expected direction, and within 20 years nearly reaches the computed steady-state extents.

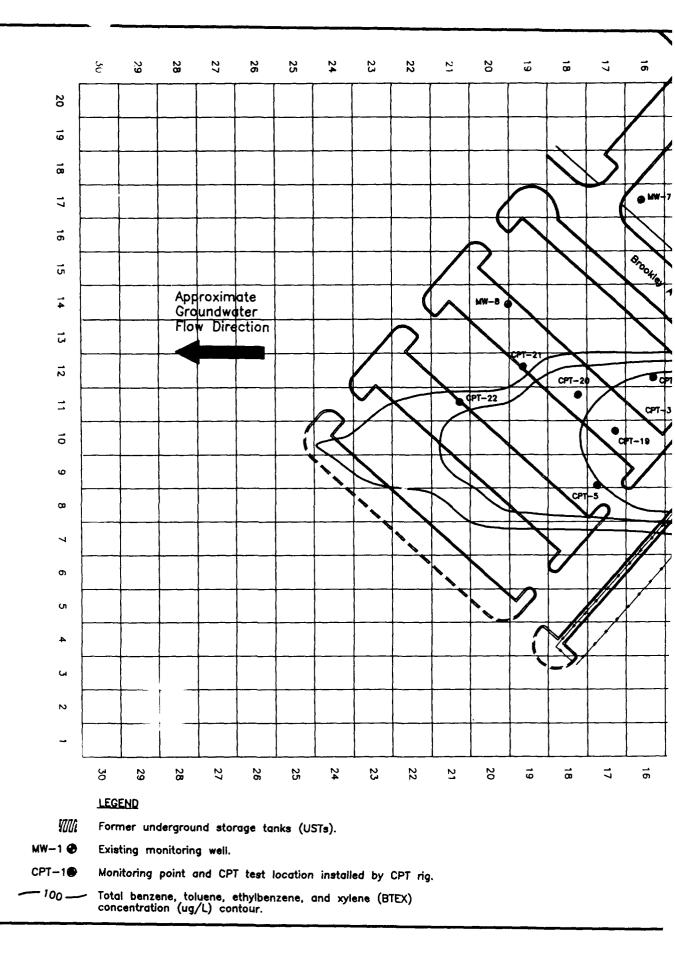

In order to verify the results of model CAL2, Parsons ES calculated a first-order decay coefficient using methods specified by Wiedemeier et al. (1994) and site specific data. An analytical model (Bear, 1979) was utilized which incorporates one-dimensional advection, dispersion, retardation, and first-order decay. As discussed in previous report sections, calculated rate constants for the Car Care Center Site (Building 41) ranged from 0.0001 to 0.0004 day⁻¹. This value is low as compared to typical literature values. However, this result may be valid because a low groundwater flow velocity (22 feet/yr) was calculated for this site. A major controlling factor for the rate of biodegradation is the quantity of electron acceptors which are flushed from upgradient areas through the contaminated zone.

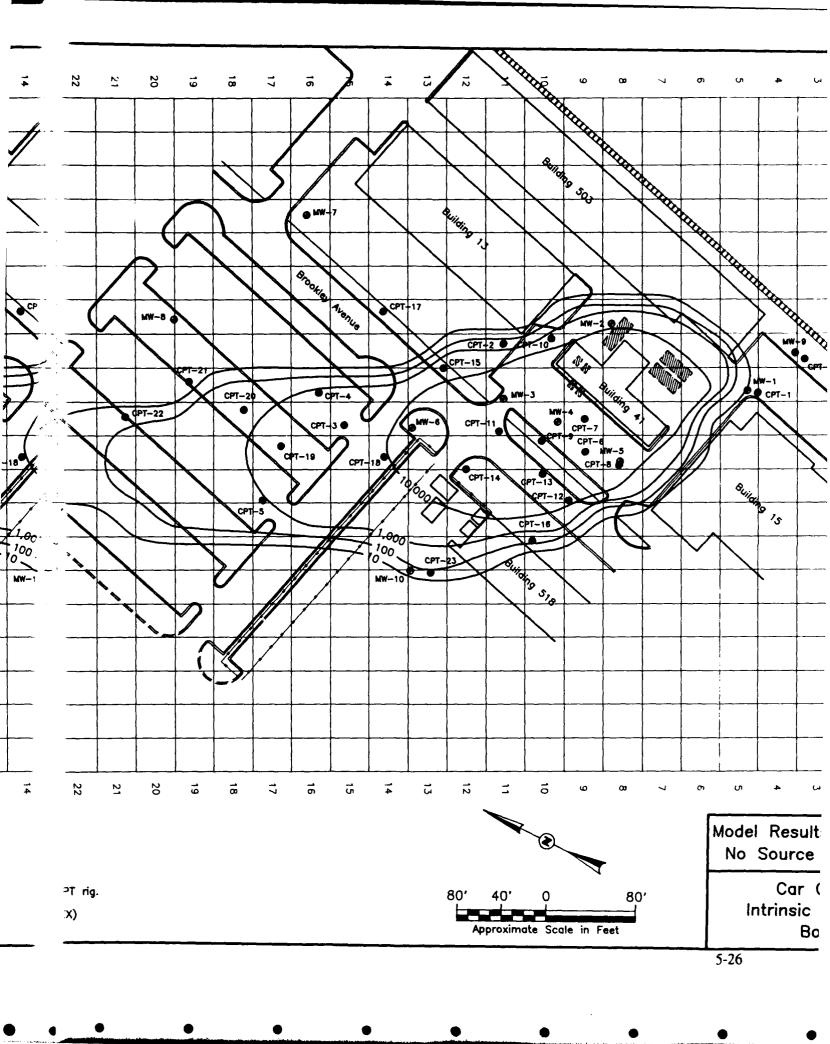

72245053.dwg / ps:1=1 / 1-26-95 / TLP

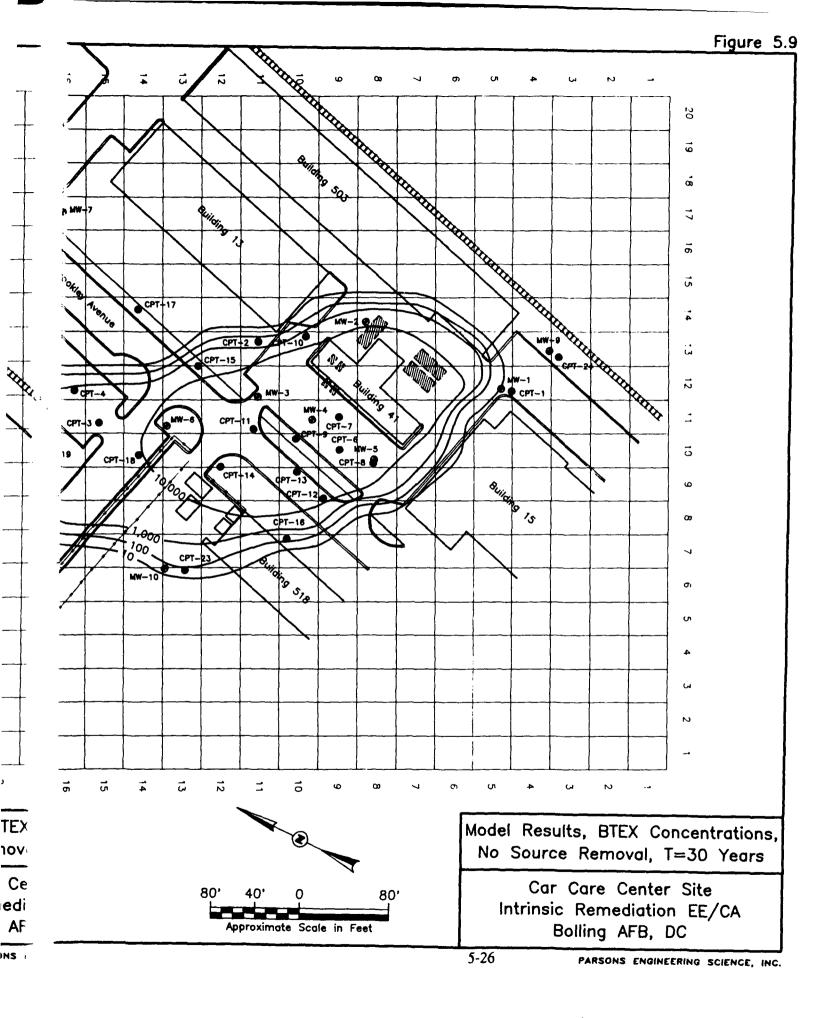

1245053.dwg / ...i=1 / 1-26-95 / TLP

A comparison between numerical and analytical model results was performed to validate the CAL2 model input parameters. Analytical model results are provided in Appendix D. Parsons ES utilized CPT-11 as the source area within the model because it had the highest BTEX concentration among wells at the Car Care Center Site and it is approximately located at the most downgradient extent of the residual LNAPL plume (Figure 4.2a). Model CAL2 suggests that the BTEX will achieve steady-state at approximately 460 feet downgradient from this location. Analytical model results (Appendix D) agree favorably with the CAL2 model results. The analytical model which incorporates advection, dispersion, retardation, and a first-order decay coefficient of 0.0003 day⁻¹ compares closely with the CAL2 model results.

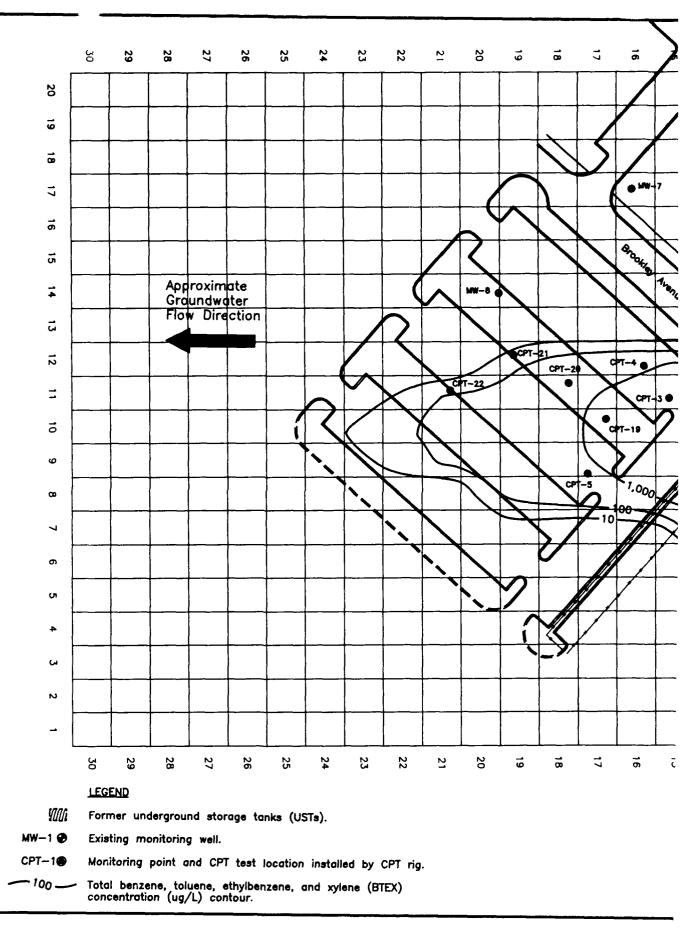

5.6.2 Twenty-Percent Annual Source Removal (Model SR20)

Model SR20 simulated the migration and biodegradation of the BTEX plume assuming a linear 20-percent annual reduction in source BTEX concentrations resulting from natural weathering processes and limited source removal through a remedial option such as bioventing. Model SR20 is identical to model CAL2 with the exception of the 20-percent annual source removal term. The concentration of hydrocarbons introduced into the system by the injection wells was reduced by 20 percent of the original amount per year for 5 years. The BTEX plume extent for years 1 through 4 of this simulation were nearly identical to those predicted in model CAL2; however, source area concentrations were predicted to decrease.

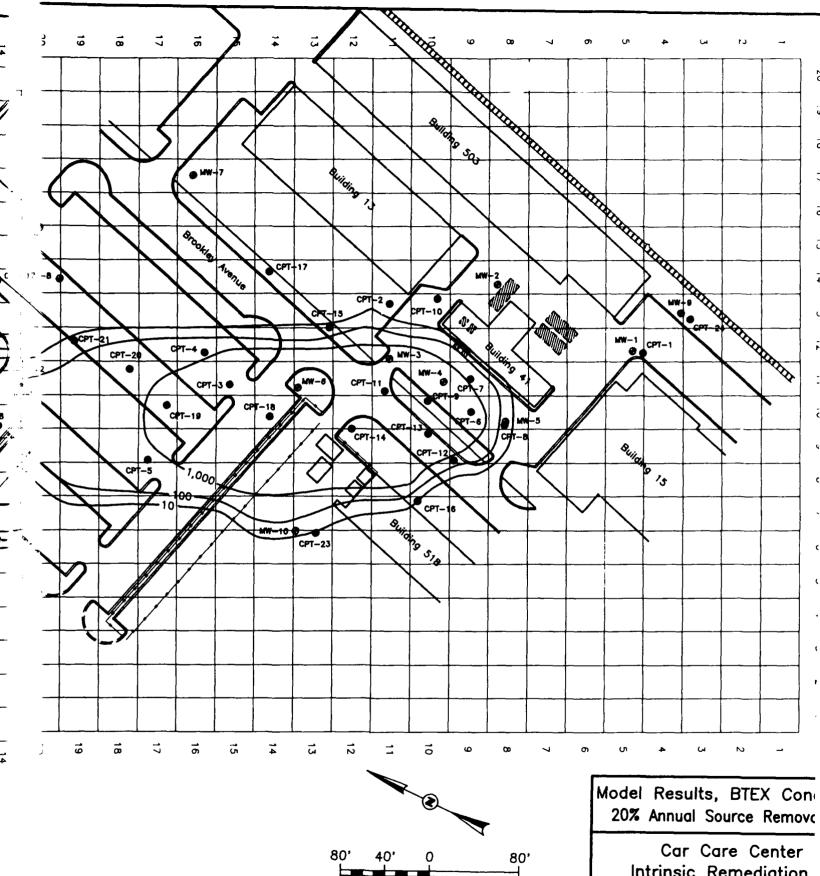

Figures 5.10 and 5.11 show the results of this model for 7 years and 10 years after initiating source removal, respectively. Seven years after initiation of source removal (Figure 5.10), the plume had receded noticeably and the maximum BTEX concentration was reduced to 3,783 μ g/L. Ten years after initiation of source removal (Figure 5.11), the plume was approximately 30 percent of its original area and the center of the plume moved approximately 240 ft downgradient from the center of the source area. At that time, the maximum predicted concentration of BTEX was only 574 μ g/L. After 13 years since initiation of source removal, the maximum BTEX concentration in the center of the plume decreased to 66 μ g/L. The simulated BTEX plume had not migrated any further downgradient. This suggests DCRA target cleanup levels will be met within 13 years under this model scenario. Within 15 years after initiation of source removal, the BTEX plume disappears completely prior to reaching the downgradient end of the model grid (approximately 700 ft downgradient of the original plume center).

5.6.3 Thirty-Three-Percent Annual Source Removal (Model SR33)

Model SR33 simulated the migration and biodegradation of the BTEX plume assuming a 33-percent annual reduction in source BTEX concentrations resulting from natural weathering processes and more active source removal through a combination of remedial alternatives such as SVE, biosparging, and/or bioventing. Model SR33 is identical to model CAL2 with the exception of the 33-percent annual source removal term. Figures 5.12 and 5.13 show the results of this model at 5 and 11 years after initiation of source removal. The model predicted an approximate 25 percent reduction in BTEX plume area 5 years after initiation of source removal (Figure 5.12). At that time, the maximum predicted BTEX concentration was 5,768 μ g/L. At 11 years after

initiation of source removal (Figure 5.13), the center of the plume has migrated approximately 280 ft downgradient and the peak concentration in the center of the plume is only 113 μ g/L. Model SR33 output for times greater than 11 years suggest that the BTEX plume will not migrate any further downgradient. This suggests DCRA target cleanup levels will be met within 11 years under this model scenario. Within 13 years after initiation of source removal, the BTEX plume disappears completely prior to reaching the downgradient end of the model grid plume. As a result, it is doubtful that the BTEX plume will ever reach the Potomac River, the closest potential downgradient receptor point.

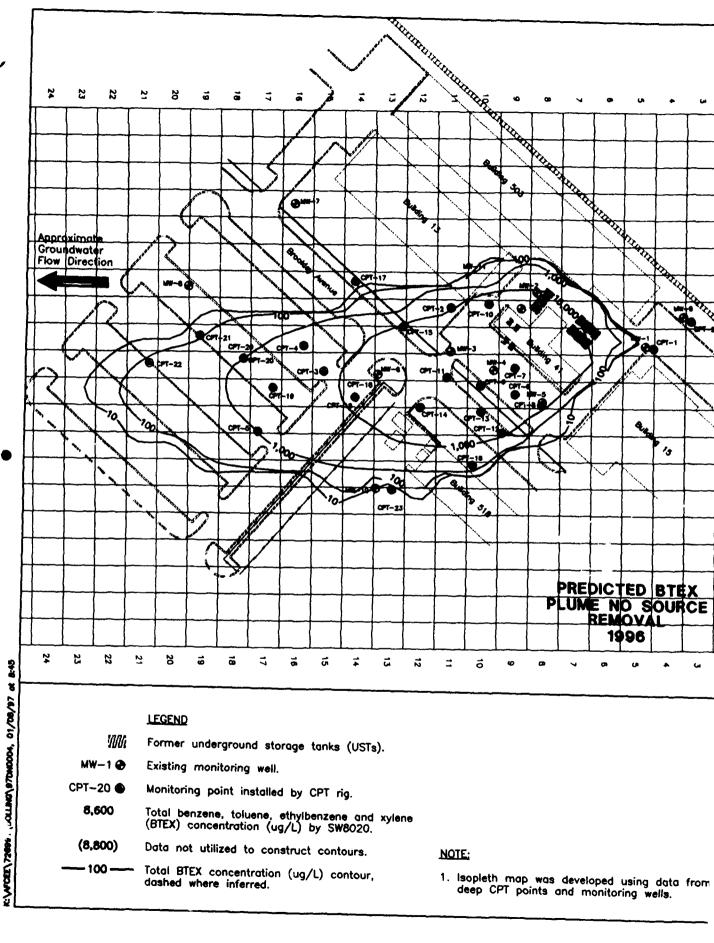

5.6.4 Observed Contaminant Plume versus Model Predictions

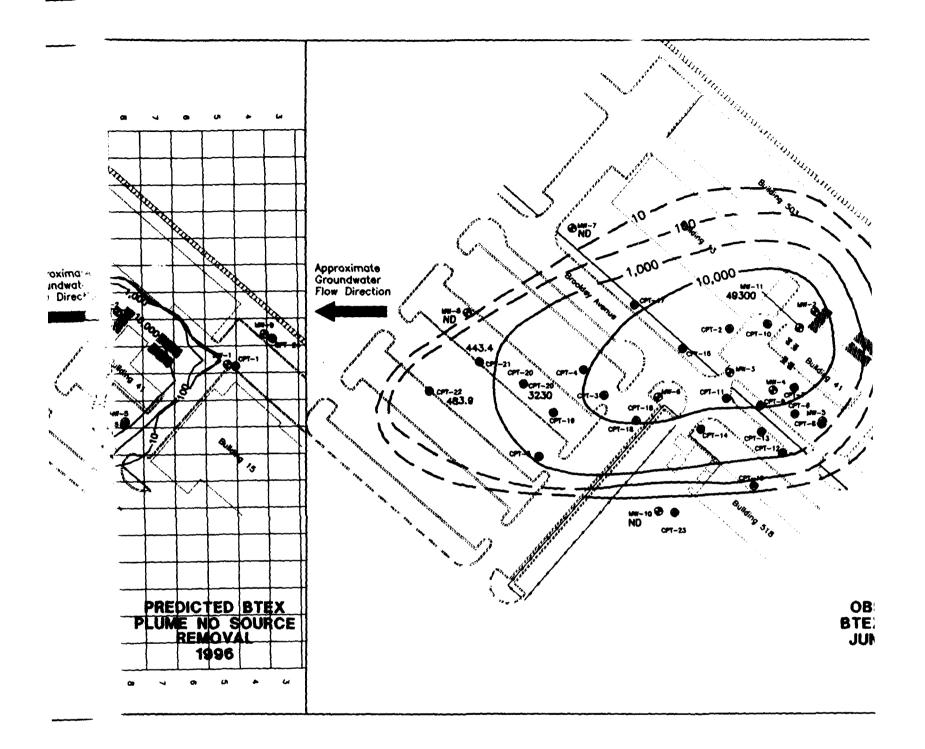

Groundwater data collected in June 1996 allows for the direct comparison of observed contaminant plume migration and predicted model results. Even though no active remediation has occurred since the August 1994, the observed dissolved BTEX plume in June 1996 (Figure 4.4) indicates that source area concentrations have decreased while the leading edge of the plume has migrated slightly to the northwest. Figure 5.14 presents the predicted contaminant plume for the year 1996 assuming no source removal alongside the observed contaminant plume from June 1996. Both the slight decrease in source area concentrations and the minimal northwesterly migration of the leading edge of the June 1996 BTEX plume are very similar to the predicted 1996 plume assuming no source removal. Using CPT-19, CPT-20, CPT-21, and CPT-22 as points of comparison, the observed increase in dissolved contamination near the leading edge of the plume, in June 1996, seems to slightly exceed model predictions for the downgradient migration distance of the 10,000 μ g/L, 1,000 μ g/L, and 100 μ g/L isopleths in two years.

With the implementation of a new source removal technology, i.e. SVE system, the dissolved contaminant plume is expected to decrease significantly within the next two years (the expected running time of SVE operations). In November 1996 a SVE system was installed at the former Car Care Center. SVE operations are expected to significantly decrease TVPH concentrations in source area soils by 1998, which in turn should reduce the dissolution of additional fuel constituents to groundwater and consequently limit the migration of water soluble fuel hydrocarbons in the site groundwater. With the start-up of the SVE system, the dissolved BTEX plume will begin to respond similarly to model predictions for the 20 to 33 percent annual source removal scenarios presented in Figures 5.10 and 5.11.

5.7 Conclusions

The results of three Bioplume II model scenarios for the former Car Care Center Site (Building 41) suggest that the dissolved BTEX plume front is not likely to migrate more than 100 feet downgradient from its August 1994 position. The first scenario, model CAL2, conservatively assumed that conditions that produced the calibrated model would remain constant (i.e., there would be no reduction in source loading). The second and third scenarios (models SR20 and SR33, respectively) assumed that source area remediation would reduce BTEX loading rates. CAL2 results suggest that within 30 years, the BTEX plume will reach its maximum extent, approximately 460 feet downgradient from the northwest property boundary along Brookley Avenue,

before stabilizing. Results of SR20 and SR33 suggest that after source reduction and removal, the BTEX plume will migrate no more than 450 feet from the northwest property boundary along Brookley Avenue before the BTEX concentrations decrease below 1 μ g/l. Model simulations conducted during this project are extremely conservative for several reasons, including the following:

- 1) Aerobic respiration, denitrification, iron reduction, sulfate reduction, and methanogenesis are all occurring at this site; however, only DO and nitrate are considered as electron acceptors during model simulations;
- 2) The stoichiometry used to determine the ratio between DO plus nitrate-equivalent DO and BTEX assumed that no microbial cell mass was produced during the reaction. As discussed in Section 4.3.2.1, this approach may be conservative by a factor of three.
- 3) The highest DO concentration observed at the site was 5.2 mg/L. The highest DO concentration assumed during model simulations was 5.0 mg/L. In addition, the highest observed nitrate concentration observed at the site was 18 mg/L (as nitrogen). The highest nitrate concentration assumed during model simulations was 5 mg/L.
- 4) The lowest coefficient of retardation for benzene (1.22) was used for model simulations. Coefficient of retardation values for the other BTEX compounds range from 1.61 to 4.74. Use of the low coefficient of retardation tends to increase the distance traveled by the simulated BTEX plume, but provides a more accurate estimate of benzene transport.

Models CAL2, SR20, and SR33 represent endpoints in a continuum of probable scenarios at the Car Care Center Site. CAL2 represents the "worst case" in that it assumes BTEX dissolution into the aquifer will continue indefinitely, while BTEX loading rates should decrease as the residual product weathers and the continuing dissolution removes more and more of those compounds. Model SR20 and SR33 are more optimistic predictions that assume source remediation will result in proportional decreases in BTEX dissolution. It is likely that future site conditions will fall somewhere between these endpoints, with the plume not migrating as far as indicated by CAL2, but with BTEX in the source area persisting longer than predicted by SR20 and SR33.

SECTION 6

COMPARATIVE ANALYSIS OF REMEDIAL ALTERNATIVES

This section presents the development and comparative analysis of three groundwater remedial alternatives for the Car Care Center Site (Building 41) at Bolling AFB. The intent of this evaluation is to determine if intrinsic remediation is an appropriate and cost-effective remedial technology to consider when developing final remedial strategies for the Car Care Center Site, especially when combined with other conventional remedial technologies.

Section 6.1 presents the evaluation criteria used to assess groundwater remedial alternatives. Section 6.2 discusses the development of remedial alternatives considered as part of this demonstration project. Section 6.3 provides a brief description of each of these remedial alternatives. Section 6.4 provides a more detailed analysis of the remedial alternatives using the defined remedial alternative evaluation criteria. The results of this evaluation process are summarized in Section 6.5.

6.1 REMEDIAL ALTERNATIVE EVALUATION CRITERIA

The evaluation criteria used to identify appropriate remedial alternatives were adapted from those recommended by the USEPA (1988) for selecting remedies for Superfund sites (OSWER Directive 9355.3-01). These criteria included (1) long-term effectiveness and permanence, (2) technical and administrative implementability, and (3) relative cost. The following sections briefly describe the scope and purpose of each evaluation criterion. This report does not include a complete discussion of applicable or relevant and appropriate requirements (ARARs) for the site. Rather, this report focuses on the potential use of intrinsic remediation and source reduction technologies to reduce BTEX concentrations within the shallow groundwater to levels that do not pose unacceptable risks to human health or the environment.

6.1.1 Long-Term Effectiveness and Permanence

Each remedial technology or remedial alternative (which can be a combination of remedial technologies such as intrinsic remediation and institutional controls) was analyzed to determine how effectively it will minimize groundwater plume expansion so that groundwater quality standards can be achieved at a downgradient point of compliance (POC). The expected technical effectiveness was evaluated based on case histories from other sites with similar conditions. The ability to minimize potential impacts to surrounding facilities and operations was considered. Also, the ability of each remedial alternative to protect both current and potential future receptors from potential risks was qualitatively assessed by conservatively estimating whether a potential receptor exposure pathway involving groundwater could be completed, either

now or in the future. These evaluation criteria also include the ability for the groundwater to reduce contaminant mass, toxicity, and volume. Time to implementation and time until protection is achieved are discussed. Long-term reliability for providing continued protection, including an assessment of potential for failure of the technology and the potential threats resulting from such a failure, was also evaluated.

6.1.2 Implementability

The technical implementation of each remedial technology or remedial alternative was evaluated in terms of technical feasibility and availability. Potential shortcomings and difficulties in construction, operations, maintenance, and monitoring are presented and weighed against perceived benefits. Requirements for any post-implementation site controls such as LTM and land use restrictions are described. Details on administrative feasibility in terms of the likelihood of public acceptance and the ability to obtain necessary approvals are discussed.

6.1.3 Cost

The total cost (present worth) of each remedial alternative was estimated for relative comparison. An estimate of capital costs, and operations and post-implementation costs for site monitoring and controls is included. An annual adjustment factor of 7 percent was assumed in present worth calculations, as recommended by OSWER Directive No. 9355.3-20. The annual adjustment factor is the difference between the rate of inflation, and the cost of money (EPA, 1988).

6.2 FACTORS INFLUENCING ALTERNATIVES DEVELOPMENT

Several factors were considered during the identification and screening of remedial technologies for addressing shallow groundwater contamination at the Bolling AFB Car Care Center Site. Factors considered included the objectives of the natural attenuation demonstration program; contaminant, groundwater, and soil properties; present and future land use; and potential exposure pathways. The following sections briefly describe each of these factors and how they were used to narrow the list of potentially applicable remedial technologies to the final remedial alternatives considered for the Car Care Center Site.

6.2.1 Program Objectives

The intent of the intrinsic remediation demonstration program sponsored by AFCEE is to develop a systematic process for scientifically investigating and documenting naturally occurring subsurface attenuation processes that can be factored into overall site remediation plans. The objectives of this program and the specific Car Care Center Site study are to provide solid evidence of intrinsic remediation of dissolved fuel hydrocarbon so that this information can be used to develop an effective groundwater remediation strategy. A secondary goal of this multi-site initiative is to provide a series of regional case studies which demonstrate that natural processes of contaminant degradation can often reduce contaminant concentrations in groundwater to below acceptable cleanup standards before completion of potential exposure pathways.

Because the objective of this program is to study natural processes in the saturated zone rather than all contaminated media (soil, soil gas, etc.), technologies have been evaluated based on their potential impact on shallow groundwater and phreatic soils. Technologies that can reduce vadose zone contamination and partitioning of contaminants into groundwater also have been evaluated. Many of the source removal technologies evaluated in this section will reduce soil and soil gas contamination, but it is important to emphasize that the remedial alternatives developed in this document are not intended to directly remediate all contaminated site media. For example, remediation of contamination in the vadose zone can reduce contaminant leaching, further increasing the effectiveness of natural attenuation mechanisms.

Additional program objectives set forth by AFCEE include cost effectiveness and minimization of waste. Technologies that may meet these criteria include institutional controls, SVE, bioventing, biosparging, hydraulic containment, and intrinsic remediation. Soil excavation, slurry walls, sheet piling, carbon adsorption, ex situ biological or chemical treatment, groundwater pump and treat, and onsite/offsite disposal are not attractive technology candidates for this site.

6.2.2 Contaminant Properties

The site-related contaminants considered as part of this demonstration at the Car Care Center Site are the BTEX compounds. The source of this contamination is weathered gasoline present as residual contamination in the vadose zone, capillary fringe, and saturated soil on the Car Care Center property. The physiochemical characteristics of both gasoline and the individual BTEX compounds will greatly influence the effectiveness and selection of a remedial technology.

Petroleum hydrocarbon mixtures, such as gasoline, are comprised of over 300 compounds with different physiochemical characteristics. Gasoline is classified as an LNAPL with a liquid density of approximately 0.73 gram per cubic centimeter (g/cc) at 20°C (BEIA, 1989). Because gasoline is less dense than water, the LNAPL may become concentrated in the capillary fringe. The individual gasoline constituents can also sorb very well to the soil matrix or volatilize into soil vapor. Constituents in gasoline range from slightly to highly soluble in water. Overall solubility is approximately 300 mg/L. Gasoline is also a primary substrate for biological metabolism. Simultaneous biodegradation of aliphatic, aromatic, and alicyclic hydrocarbons has been observed. In fact, mineralization rates of hydrocarbons in mixtures, such as gasoline, may be faster than mineralization of the individual constituents as a result of cometabolic pathways (Jamison et al., 1975; Perry, 1984).

The BTEX compounds are generally volatile, highly soluble in water, and adsorb less strongly to soil than other hydrocarbons in the petroleum mixture. These characteristics allow the BTEX compounds to leach more rapidly from contaminated soil into groundwater and migrate as dissolved contamination (Lyman et al., 1992). All of the BTEX compounds are highly amenable to in situ degradation by both biotic and abiotic mechanisms.

Benzene is very volatile with a vapor pressure of 76 millimeters of mercury (mm Hg) at 20°C and a Henry's Law Constant of approximately 0.0054 atmosphere-cubic meters per mole (atm-m³/mol) at 25°C (Hine and Mookerjee, 1975; Jury et al., 1984).

The solubility of pure benzene in water at 20°C has been reported to be 1,780 mg/L (Verschueren, 1983). Benzene is normally biodegraded to carbon dioxide, with catechol as a short-lived intermediate (Hopper, 1978; Ribbons and Eaton, 1992).

Toluene is also volatile, with a vapor pressure of 22 mm Hg at 20°C and a Henry's Law Constant of about 0.0067 atm-m³/mol at 25°C (Pankow and Rosen, 1988; Hine and Mookerjee, 1975). Toluene sorbs more readily to soil media relative to benzene, but still is very mobile. The solubility of pure toluene in water at 20°C is approximately 515 mg/L at 20°C (Verschueren, 1983). Toluene has been shown to degrade to pyruvate, acetaldehyde, and completely to carbon dioxide via the intermediate catechol (Hopper, 1978; Wilson et al., 1986; Ribbons and Eaton, 1992).

Ethylbenzene has a vapor pressure of 7 mm Hg at 20°C and a Henry's Law Constant of 0.0066 atm-m³/mol (Pankow and Rosen, 1988; Valsaraj, 1988). Ethylbenzene sorbs more strongly to soils than benzene but less strongly than toluene (Abdul et al., 1987). Pure ethylbenzene is also less soluble than benzene and toluene in water at 152 mg/L at 20°C (Verschueren, 1983; Miller et al., 1985). Ethylbenzene ultimately degrades to carbon dioxide via its intermediate 3-ethylcatechol (Hopper, 1978; Ribbons and Eaton, 1992).

The three isomers of xylene have vapor pressures ranging from 7 to 9 mm Hg at 20°C and Henry's Law Constants of between 0.005 and 0.007 atm-m³/mol at 25°C (Mackay and Wolkoff, 1973; Hine and Mookerjee, 1975; Pankow and Rosen, 1988). Of all of the BTEX compounds, xylenes sorb most strongly to soil, but still can leach from soil into the groundwater (Abdul et al., 1987). Pure xylenes have water solubilities of 152 to 160 mg/L at 20°C (Bohon and Claussen, 1951; Mackay and Shiu, 1981; Isnard and Lambert, 1988). Xylenes can degrade to carbon dioxide via pyruvate carbonyl intermediates (Hopper, 1978; Ribbons and Eaton, 1992).

Based on these physiochemical characteristics, intrinsic remediation, SVE, bioventing, biosparging, and groundwater extraction/air stripping technologies could all be effective at collecting, destroying, and/or treating BTEX contaminants at the Car Care Center Site.

6.2.3 Site-Specific Conditions

Two general categories of site-specific characteristics were considered when identifying remedial technologies for comparative evaluation as part of this demonstration project. The first category was physical characteristics such as groundwater depth, gradient, flow direction, and soil type, which influence the types of remedial technologies most appropriate for the site. The second category involved assumptions about future land use and potential exposure pathways. Each of these site-specific characteristics have influenced the selection of remedial alternatives included in the comparative evaluation.

6.2.3.1 Groundwater and Soil Characteristics

Site geology and hydrogeology will have a profound effect on the transport of contaminants and the effectiveness and scope of required remedial technologies at a given site. Hydraulic conductivity is perhaps the most important aquifer parameter

governing groundwater flow and contaminant transport in the subsurface. The velocity of the groundwater and dissolved contamination is directly related to the hydraulic conductivity of the saturated zone. Rising head slug tests, completed at the Car Care Center Site during January 1994 (Baker, 1994), indicated that hydraulic conductivity of the shallow aquifer ranged from 5.8 x 10⁵ to 5.8 x 10⁶ ft/sec. These values, when utilized in a contaminant transport model, did not adequately reproduce the observed plume extent. In order to delop a more representative transport model, Parsons ES ge hydraulic conductivity value (1.44 x 10⁻⁴ ft/sec) utilized a slightly higher a within this model. Howe, hydraulic conductivity values within the model ranged from 1.7 x 10⁴ to 3.4 x 10⁶ ft/sec (see Section 5.4.1). These values are characteristic of the aguifer materials (see Sections 3 and 5 of this report) observed at the site. The average hydraulic conductivity in combination with the relatively flat hydraulic gradient observed at this site yields a groundwater flow velocity of 22 ft/year. This moderate velocity directly influences the fate and transport of contaminants by limiting the rate of contamination migration. As a result, the shallow groundwater plume has migrated relatively slowly at the site.

Although a moderate hydraulic conductivity can result in some plume expansion and migration, this same characteristic will also enhance the effectiveness of other remedial technologies, such as groundwater extraction, biosparging, and intrinsic remediation. For example, it should be less expensive and time-consuming to capture and treat the contaminant plume using a network of extraction wells in areas of moderate to high hydraulic conductivity. The effectiveness of biologing may also be increased in sandy aquifers because of reduced entry press increased radius of influence. Greater hydraulic conductivity also increases the and of contaminant mass traveling through the biosparging network. Contaminant recovery may also be maximized when contaminants are not significantly sorbed to and retarded by phreatic soil. The relatively low TOC content of Bolling AFB aquifer materials (0.06 to 0.15 percent) will tend to minimize sorption and allow mobility of BTEX compounds

The movement of contaminants within the subsurface away from the course will also increase the effectiveness of natural biodegradation processes by distributing the contaminant mass into areas enriched with electron acceptors. To satisfy the requirements of indigenous microbial activity and intrinsic remediation, the aquifer must also provide an adequate and available carbon or energy source, electron acceptors, essential nutrients, proper ranges of pH, temperature, and redox potential.

Data collected as part of the field work phase of this demonstration project and described in Sections 3 and 4 of this document indicate that the Car Care Center Site is characterized by adequate and available carbon/energy sources and electron acceptors that support measurable biodegradation of gasoline contamination by indigenous microorganisms. Dissolved sulfate, carbon dioxide (which is utilized during methanogenesis), oxygen, and nitrate represent significant sources of electron acceptor capacity for the biodegradation of BTEX compounds at the site. Further, because fuel hydrocarbon-degrading microorganisms have been known to thrive under a wide range of temperature and pH conditions (Freeze and Cherry, 1979), the physical and chemical conditions of the groundwater and phreatic soil at the Car Care Center Site are not likely to inhibit microorganism growth.

Fuel hydrocarbon-degrading microorganisms are ubiquitous, and as many as 28 hydrocarbon-degrading isolates (bacteria and fungi) have been discovered in different soil environments (Davies and Westlake, 1979; Jones and Eddington, 1968). Indigenous microorganisms have a distinct advantage over microorganisms injected into the subsurface to enhance biodegradation because indigenous microorganisms are well adapted to the physical and chemical conditions of the subsurface in which they reside (Goldstein et al., 1985). Microbe addition was not considered a viable remedial technology for the Car Care Center Site.

6.2.3.2 Potential Exposure Pathways

An exposure pathway analysis identifies the potential human and ecological receptors that could potentially come into contact with site-related contamination and the pathways through which these receptors might be exposed. To have a completed exposure pathway, there must be a source of contamination, a potential mechanism(s) of release, a pathway of transport to an exposure point, an exposure point, and a receptor. If any of these elements do not exist, the exposure pathway is considered incomplete, and receptors will not come into contact with site-related contamination. Evaluation of the potential long-term effectiveness of any remedial technology or remedial alternative as part of this demonstration project includes determining if the approach will be sufficient and adequate to minimize plume expansion so that potential exposure pathways involving shallow groundwater are incomplete.

Assumptions about current and future land use at a site form the basis for identifying potential receptors, potential exposure pathways, reasonable exposure scenarios, and appropriate remediation goals. USEPA (1991) advises that the land use associated with the highest (most conservative) potential level of exposure and risk that can reasonably be expected to occur should be used to guide the identification of potential exposure pathways and to determine the level to which the site must be remediated. The source area consists of fuel storage facilities that are now defunct, and retail facilities associated with the former Car Care Center. The groundwater plume originating from the Car Care Center is migrating to the northwest, and has impacted shallow groundwater in an area extending from the source area to the parking lot across Brookley Avenue (Figure 4.4). The parking lots located northwest of the Car Care Center and across Brookley Avenue overlie most of the contaminant plume. Warehouses, roadways, maintenance buildings, and office buildings are located on The current land use within and downgradient from the adjacent properties. contaminant plume is entirely industrial.

Under reasonable current land use assumptions, potential receptors include only worker populations. It is unlikely that workers could be exposed to site-related contamination in phreatic soils or shallow groundwater unless this material is removed during future construction excavations or remedial activities. As groundwater is located at a depth of approximately 18 to 20 feet bls, it is unlikely that utility workers could be exposed to shallow groundwater contamination. Shallow groundwater is not currently used to meet any water supply demands at Bolling AFB. All on-base water supply demands are met by water piped in from the Blue Plains Water Treatment Facility located south of Bolling AFB. Exposure pathways involving other environmental media such as shallow soils and soil gas in the source area were not considered as part of this project, but should be considered in overall site remediation

decisions. In the event future construction activities are planned for the Car Care Center Site (Building 41), special precautions should be taken to ensure environmental safety and limit worker exposure.

Migration of contaminated shallow groundwater resulting in a discharge into the Potomac River could complete an exposure pathway to human or ecological receptors via dermal contact or possible ingestion. However, it is very unlikely that detectable concentrations could reach the river. The Potomac River is located approximately 2,800 feet downgradient from the leading edge of the contaminant plume. A conservative tracer would require approximately 130 years to reach the river. However, fate and transport modeling suggests that the contaminant plume will not travel this distance due to natural attenuation. In the unlikely event that contaminants reach the Potomac River, BTEX concentrations probably will be instantly diluted to below analytical detection limits.

Assumptions about hypothetical future land uses must also be made to ensure that the remedial technology or alternative considered for shallow groundwater at the site is adequate and sufficient to provide long-term protection. No changes in land use are anticipated in the foreseeable future, so a continued industrial land use assumption is appropriate. As a result, potential future receptors include only worker populations. The potential future exposure pathways involving workers are identical to those under current conditions provided shallow groundwater is not used to meet industrial water demands. In summary, the use of intrinsic remediation technology at this site will require that the source area be maintained as industrial property and that restrictions on groundwater use be enforced in areas downgradient of the Car Care Center Site to the Potomac River. If source removal technologies such as SVE, bioventing, LNAPL recovery, biosparging, or groundwater pump and treat are implemented, they will have some impact on the short- and long-term land use options and will require some level of institutional control and worker protection during remediation.

6.2.3.3 Remediation Goals for Shallow Groundwater

Model results suggest that BTEX compounds are not likely to move more that 460 feet downgradient from the source area (measured from the northwest property boundary along Brookley Avenue), assuming contaminants are introduced into the aquifer at a constant rate. Without source removal, the contaminant plume should reach steady-state conditions within 30 years. As source area remediation proceeds, and as residual LNAPL weathers, BTEX loading rates will decrease, and the extent of BTEX migration will likely be much more limited. Therefore, a location of approximately 650 to 700 feet beyond the northwest property has been identified as the POC for groundwater remedial activities because this appears to be the maximum extent of future contaminant migration. This is a suitable location for monitoring and for demonstrating compliance with protective groundwater quality standards, such as promulgated federal MCLs or DCRA target cleanup criteria.

This remedial strategy assumes that compliance with promulgated, single-point remediation goals is not necessary if site-related contamination does not pose a threat to human health or the environment (i.e., the exposure pathway is incomplete). Thus, the magnitude of required remediation in areas that can and will be placed under institutional control is different from the remediation that is required in areas that may

be available for unrestricted use. The primary RAO for shallow groundwater within and downgradient of the Car Care Center Site is minimizing plume expansion to prevent exposure of downgradient receptors to concentrations of BTEX in groundwater at levels that pose a risk. This means that viable remedial alternatives must be able to achieve concentrations that minimize plume migration and/or expansion. The RAO for shallow groundwater at the POC is attainment of DCRA's target cleanup levels and federal drinking water MCLs for each of the BTEX compounds listed in Table 6.1. Although it is unlikely that groundwater would be ingested by humans, this level of long-term protection is appropriate, because the shallow groundwater in this area is classified by DCRA as a potential potable water source.

In summary, available data suggest that there is no complete potential exposure pathway at the Car Care Center Site under current conditions. It is not likely that potential exposure pathways involving shallow groundwater would be complete under future land use assumptions, provided use of groundwater as a potable or industrial source of water is prohibited by institutional controls within the source area and approximately 700 feet downgradient from the source area (measured from the northwest site property boundary along Brookley Avenue). Thus, institutional controls are likely to be a necessary component of any groundwater remediation strategy for this site. The required duration of these institutional controls may vary depending on the effectiveness of the selected remedial technology at reducing contaminant mass and concentration in the groundwater.

6.2.4 Summary of Remedial Technology Screening

Several remedial technologies have been identified and screened for use in treating the shallow groundwater at the Car Care Center Site. Table 6.2 identifies the initial remedial technologies considered as part of this demonstration and those retained for detailed comparative analysis. Screening was conducted systematically by considering the program objectives of the AFCEE intrinsic remediation demonstration, physiochemical properties of the BTEX compounds, and other site-specific characteristics such as hydrogeology, land use assumptions, potential exposure pathways, and appropriate remediation goals. All of these factors will influence the technical effectiveness, implementation, and relative cost of technologies for remediating shallow groundwater underlying and migrating from the site. The remedial technologies retained for development of remedial alternatives and comparative analysis include institutional controls, intrinsic remediation, LTM, bioventing, SVE, mobile LNAPL removal, and biosparging.

6.3 BRIEF DESCRIPTION OF REMEDIAL ALTERNATIVES

This section describes how remedial technologies retained from the screening process were combined into two remedial alternatives for the Car Care Center Site. Sufficient information on each remedial alternative has been provided to facilitate a comparative analysis of effectiveness, implementability, and cost in Section 6.4.

6.3.1 Alternative 1 - Passive Mobile LNAPL Removal, Intrinsic Remediation, and Institutional Controls with Long-Term Groundwater Monitoring

In the past, Bolling AFB employed a contractor to hand-bail mobile LNAPL from site monitoring wells. However, this practice was discontinued in May 1994 due to the minimal mobile LNAPL that was being recovered. Manual removal of small quantities of product from site wells was costly and time consuming, with little overall benefit. Under Alternative 1, LNAPL removal would commence in select wells (i.e., those containing product) using passive, in-well, product-selective passive skimmers. These devices will continuously "bail" floating product from a well. The passive skimmers typically have a collection chamber on the bottom of the skimmer to hold recovered product. The canisters would be emptied manually on an as-needed basis.

Passive remediation would continue through intrinsic remediation mechanisms. Intrinsic remediation is achieved when naturally occurring attenuation mechanisms bring about a reduction in the total mass of a contaminant in the soil or dissolved in groundwater. Intrinsic remediation results from the integration of several subsurface attenuation mechanisms that are classified as either destructive or nondestructive. Destructive attenuation mechanisms include biodegradation, abiotic oxidation, and hydrolysis. Nondestructive attenuation mechanisms include sorption, dilution (caused by dispersion and infiltration), and volatilization. In some cases, intrinsic remediation will reduce dissolved contaminant concentrations below numerical concentration goals, thus protecting human health and the environment. Based on the existing evidence of intrinsic remediation described in Section 4, these processes are occurring at the Car Care Center Site and will continue to reduce contaminant mass in the plume area.

Model CAL2 assumes that the residual LNAPL will be a continuous constant source of contaminants. In reality, the hydrocarbon leaching rate will diminish over time. In addition, the model assumes that intrinsic remediation is the sole removal mechanism for contaminant mass in the subsurface; however, passive LNAPL removed is included as a component of this alternative. As a result, the continuous source assumption provides a conservative estimate. Actual plume dimensions will likely be smaller than those predicted herein. As indicated in Section 5.6.1, model CAL2 results suggest that intrinsic remediation will stabilize the BTEX plume within 25 to 30 years. The plume could extend to a maximum of 460 feet downgradient (Figure 5.9) from the source area (as measured from the northwest property boundary along Brookley Avenue).

Implementation of Alternative 1 would require the use of institutional controls such as land use restrictions and LTM. Land use restrictions may include placing long-term restrictions on soil excavation within the source area and long-term restrictions on groundwater well installations within and downgradient of the source area. The intent of these restrictions would be to reduce potential receptor exposure to contaminants by legally restricting activities within areas affected by site-related contamination.

As a minimum, groundwater monitoring would be conducted twice annually for 30 years as part of this remedial technology to evaluate the progress of natural attenuation processes. Based on the potential plume migration suggested by model CAL2, it is unlikely that benzene concentrations exceeding the DCRA target cleanup level of 5 μ g/L would be present more that 460 feet downgradient of the source area as measured from the property boundary along Brookley Avenue. This would be true even if it

were assumed that model contaminant concentrations are all benzene rather than total BTEX.

Because there are no apparent downgradient receptors, POC wells should be placed 300 to 400 feet downgradient of the modeled maximum plume extent (i.e., approximately 700 feet downgradient of the Car Care Center western property boundary along Brookley Avenue). In addition, LTM wells within, upgradient, and immediately downgradient from the existing BTEX plume will be used to monitor the effectiveness of intrinsic remediation. LTM wells are further described in Section 7.2.1. Detection of benzene in excess of 5 μ g/L at the POC wells may require additional evaluation and modeling to assess BTEX migration, or to determine if additional corrective actions would be necessary. Land use restrictions would also require reevaluation.

Public education on the selected alternative will be developed to inform base personnel and local residents of the scientific principles underlying source reduction and intrinsic remediation. This education could be accomplished through public meetings, presentations, press releases, and posting of signs where appropriate. Periodic site reviews could also be conducted every year using data collected from the long-term groundwater monitoring program. The purpose of these periodic reviews will be to evaluate the extent of contamination, assess contaminant migration and attenuation through time, document the effectiveness of source removal and institutional controls, and reevaluate the need for additional remedial actions.

6.3.2 Alternative 2 - Passive Mobile LNAPL Removal, Bioventing in the Source Area, Intrinsic Remediation, and Institutional Controls with Long-Term Groundwater Monitoring

Pilot-scale bioventing tests have been conducted at two separate locations on Bolling AFB. These study areas include the Heat Plant (Building 18) and the Former Tank Farm located across from Building 5300. These tests were initiated during 1993, and have operated for approximately 1 year. Preliminary results from these studies indicate that bioventing may be an appropriate remedial technology at the Car Care Center Site due to the sandy soil conditions and deep soil contamination. A soil gas study would be required at the Car Care Center Site during the pilot study to determine whether oxygen-limited conditions exist in vadose zone soils. A vent well and vapor monitoring points would be installed during the soil gas study in order to conduct the pilot test. Upon completion of the soil gas study, a pilot study would then be performed to determine oxygen and hydrocarbon utilization rates. Pilot study results would be used to design a full-scale bioventing system capable of remediating the residual LNAPL contained in the unsaturated zone.

During design of a bioventing system, caution must be taken to ensure that the air injection process will not force volatile hydrocarbon vapors into surrounding buildings and sumps. Because numerous buildings exist within and adjacent to the Car Care Center, engineered controls must be provided to ensure health and safety of Base personnel and property.

On the basis of successful interim results of the Heat Plant (Building 18) and/or Former Tank Farm bioventing projects, a bioventing system can be conceptualized for

the Car Care Center Site. In order for the bioventing system to be effective, it must be capable of introducing oxygen (air) to the subsurface at sufficient rates in order to promote in situ biodegradation of hydrocarbons in the vadose zone. A typical full-scale bioventing system for the Car Care Center Site might consist of a series of vertical or horizontal air-injection wells installed on the facility's property throughout the vadose zone where residual LNAPL contamination is present (Figures 4.2a and 4.2b). A small blower would provide a suitable volumetric air flow rate necessary to oxygenate soils. This treatment will reduce the mass of hydrocarbon leaching into groundwater, increasing the effectiveness of natural attenuation mechanisms.

Model SR20 assumes significant BTEX loading rate reductions can occur due to bioventing. In model SR20, the source is reduced by 20 percent of the original amount per year for a 5-year period. This time period is conservative for remediation systems such as bioventing. After 5 years of source removal, the Bioplume II model predicts that the combination of source reduction and intrinsic remediation within the BTEX plume will significantly reduce its size and concentration. Under this scenario, model results show that it is unlikely that BTEX compounds would not migrate more than 450 feet (Figure 5.11) as measured from the northwestern property boundary along Brookley Avenue. The maximum dissolved BTEX concentrations in the plume are reduced below approximately $10 \,\mu\text{g/L}$ after 13 years of treatment.

This alternative is identical to Alternative 1 except that bioventing was implemented in order to remediate the residual LNAPL contamination located within the Car Care Center property. As with Alternative 1, institutional controls and LTM would be required. Due to the shorter time frame, semi-annual groundwater monitoring will continue only for 13 years. POC wells would be installed in the same locations indicated in the previous section.

6.3.3 Alternative 3 - Passive Mobile LNAPL Removal, Soil Vapor Extraction with Off-Gas Treatment, Bioventing in Source Area, Intrinsic Remediation, and Institutional Controls with Long-Term Groundwater Monitoring

This alternative is identical to Alternative 2 except that SVE would be used in combination with bioventing. Initially, SVE would be used to reduce high VOC concentrations in the primary source areas of the site (e.g., the former 12,000-gallon UST location, and west of Building 41). Bioventing alone (Alternative 2) may have a detrimental affect of forcing VOCs into surrounding buildings and sumps. During SVE, soil-gas vapors are drawn towards the vent well, minimizing the potential for off-site migration of vapors. SVE is typically operated at higher flow rates than bioventing. As a result, SVE can remove greater quantities of VOCs from subsurface soils. Because SVE is a more aggressive treatment remedy, implementing this alternative can shorten the required remediation time period.

A primary difference between SVE and bioventing is the rate at which air is moved through the subsurface. Bioventing employs low air flow rates, supplying oxygen to the subsurface to promote biodegradation, whereas SVE utilizes larger air volumes to optimize volatilization. Due to the high levels of VOCs at the site, bioventing alone may not supply adequate oxygen to the subsurface. Contaminant loading rates would eventually decrease, but more slowly than if SVE, and bioventing were combined. As a result, bioventing could be optimized by initially operating the bioventing system in a

SVE mode to remove the high concentrations of VOCs. Due to the reaeration process, SVE and bioventing may also increase the DO content of the groundwater and promote more rapid degradation of BTEX compounds in the plume and in saturated soil.

After the initial VOC concentrations in the primary source areas are reduced, a bioventing system could easily be combined with the SVE system, or used alone. Bioventing would be implemented at this site by injecting air several feet above the groundwater surface, allowing air (oxygen) to move upward through the vadose zone. If needed, SVE would then be utilized to extract the hydrocarbons volatilized from the subsurface, effectively controlling the migration of soil vapors.

VOC concentrations in the effluent of the SVE system initially are expected to be high. As a result, off-gas treatment is assumed to be necessary. Numerous effective methods exist for treating VOC emissions, including thermal treatment, catalytic oxidation (CatOx), and activated carbon adsorption. As part of an innovative technology evaluation initiative, AFCEE has demonstrated the effectiveness of using a modified internal combustion engine (ICE) to simultaneously recover and treat VOC laden soil gas. The hydrocarbon vapors recovered from a well are utilized by the ICE unit as a source of fuel. The combustion process within the ICE unit creates a vacuum and powers the SVE process. In the event that the extracted soil gas does not contain adequate thermal value, then a supplemental fuel is added (e.g., liquid-propane [LP] gas or natural gas). Through evaluation of the ICE system and other applicable technologies, AFCEE has determined that this method can be very effective at reducing VOC emissions.

Model SR33 was run to simulate this alternative. Model SR33 is similar to model SR20, except model SR33 assumes more rapid reductions in the hydrocarbon loading rates to simulate a more aggressive treatment alternative such as SVE in combination with bioventing, and passive skimming. This combined treatment system was assumed to be capable of removing residual LNAPL contamination from the primary source areas in approximately 3 years. As a result, in model SR33, the source is reduced by 33 percent of the original amount every year for 3 years. After 3 years of source removal, the Bioplume II model predicts that combining source reduction and intrinsic remediation will significantly reduce the size and concentration of the BTEX plume. Under this scenario, model results show that it is unlikely that BTEX compounds would migrate more than 425 feet (Figure 5.13) from the northwestern property boundary along Brookley Avenue. This distance is similar to the distance predicted by bioventing alone (model SR20). However, the BTEX plume dissipates within 11 years.

As with Alternative 1, passive skimming, institutional controls and LTM would be required. However, due to the shorter time frame, semi-annual groundwater monitoring will continue for only 11 years. Point-of-compliance wells would be installed in the same locations indicated in the previous section.

6.4 EVALUATION OF ALTERNATIVES

This section provides a comparative analysis based on the effectiveness, implementability and cost criteria for the three previously discussed remedial alternatives. A summary of this evaluation is presented in Section 6.5.

6-17

6.4.1 Alternative 1 - Passive Mobile LNAPL Removal, Intrinsic Remediation, and Institutional Controls with Long-Term Groundwater Monitoring

6.4.1.1 Effectiveness

Section 5 of this document presents the results of the Bioplume II model completed to support the intrinsic remediation alternative at the Car Care Center Site. Continual BTEX injection into groundwater was incorporated into model CAL2 to simulate the effects of continuous leaching of hydrocarbons from the source area. The CAL2 model results suggest that natural attenuation mechanisms will limit contaminant migration and reduce contaminant mass and toxicity downgradient of the plume. Benzene concentrations should not exceed the DCRA target cleanup level at the proposed POC well locations discussed in Section 7. Groundwater monitoring at the POC wells and LTM wells will ensure the protectiveness of this alternative. In the event BTEX is detected in a POC well at concentrations that exceed DCRA target cleanup levels, this LTM plan does not cease to be protective. The Potomac River is located over 2,800 feet from the Car Care Center Site, and it is the only known potential receptor exposure point in the area. In the event BTEX is detected in POC wells, the site conditions would be reevaluated to determine whether additional remedial actions are appropriate for the site.

The effectiveness of this remedial alternative requires that excavations or drilling within the source area be conducted only by properly protected site workers. Reasonable land use assumptions for the plume area indicate that exposure is unlikely unless excavation or drilling activities bring contaminated soil to the surface. Long-term land use restrictions will be required to ensure that shallow groundwater will not be pumped or removed for potable use within and approximately 1,000 feet in all directions from the existing BTEX plume. Existing health and safety plans should be enforced to reduce risks from any proposed remedial installation and during installation of additional POC and LTM wells.

Compliance with program goals is one component of the long-term effectiveness evaluation criterion. Alternative 1 will satisfy program objectives designed to promote intrinsic remediation as a component of site remediation and to scientifically document naturally occurring processes. Alternative 1 is based on the effectiveness of naturally occurring processes that minimize contaminant migration and reduce contaminant mass over time, and the effectiveness of institutional controls. As described earlier, the Bioplume II model results suggest that naturally occurring processes will minimize further BTEX plume migration to within 460 feet downgradient of the source area as measured from the northwest property boundary along Brookley Avenue. The sensitivity analyses completed on the Bioplume II model for this site (Section 5) suggests that even under the most conservative (i.e., worst-case) conditions, the naturally occurring processes at the Car Care Center Site should reduce contaminant migration so that the maximum distance traveled by the plume is unlikely to be beyond the proposed POC wells.

Aside from the administrative concerns associated with enforcement of long-term land use restrictions and long-term groundwater monitoring programs, this remedial alternative should provide reliable, cost-effective protection. For cost comparison purposes, it was assumed that passive product skimming would operate for a period of

3 years. Because LNAPL was observed in monitoring wells MW-2 and MW-3 during the August 1994 investigation, these wells were chosen for product skimming. However, since both MW-2 and MW-3 were destroyed just after the 1994 sampling event their replacements MW-11 and MW-3R, respectively, could be used for product skimming. In the event that additional wells are added near the primary source area in conjunction with the planned remedial activities, Parsons ES also assumed that two additional wells would be used for product skimming (four total). After 3 years, any recoverable mobile LNAPL will likely be removed from all site monitoring wells. Given that minimal mobile LNAPL has been observed at the site, a 3-year duration is a realistic assumption.

For costing purposes, Parsons ES assumed intrinsic remediation and LTM will continue for a 30-year period. This time frame was chosen because this is the modeled period of time required for the plume to reach steady-state conditions, assuming no source reductions. During this time period, predicted dissolved benzene concentrations will exceed the DCRA target cleanup level within the center of the BTEX plume. However, the DCRA target cleanup level should not be exceeded at the proposed POC well locations.

6.4.1.2 Implementability

Alternative 1 is not technically difficult to implement. Passive LNAPL skimming is similar to hand-bailing, however, it is not as labor intensive. Under this alternative, additional remedial measures are not planned. Installation of POC wells and semiannual groundwater monitoring are both standard procedures. Long-term management efforts will be required to ensure that proper sampling procedures are followed. Periodic site reviews should be conducted to confirm the adequacy and completeness of LTM data and verify the effectiveness of this remediation approach. There also may be administrative concerns associated with long-term enforcement of groundwater use restrictions. Future land use within the source area may be impacted by leaving contaminated soil and groundwater in place. Regulators, Base officials, Base employees, and the public would have to be informed of the benefits and limitations of the intrinsic remediation option. Educational programs are not difficult to implement, and the initial regulatory reaction to this alternative has been positive.

6.4.1.3 Cost

The cost of Alternative 1 is summarized in Table 6.3. A more complete breakdown and present worth analysis of these costs is provided in Appendix F. Capital costs are limited to the construction of three new POC wells and one new LTM well. The total present worth cost of mobile LNAPL recovery for a period of 3 years, and implementation of the LTM plan for 30 years is \$487,000 total present worth. Also included are the costs of maintaining institutional controls and long-term groundwater monitoring for a total of 30 years.

See Appendix F for breakdown of costs and present worth analysis.

6.4.2 Alternative 2 - Passive Mobile LNAPL Removal, Bioventing in the Source Area, Intrinsic Remediation, and Institutional Controls with Long-Term Groundwater Monitoring

6.4.2.1 Effectiveness

Two additional Bioplume II models (SR20 and SR33) were performed to evaluate the effectiveness of source reductions typically associated with selected remedial alternatives. Model SR20 simulates the effects of a bioventing system that reduces the source concentration at a rate of 20 percent of the original concentration every year for 5 years. Model results suggest that if bioventing is chosen as a source reduction alternative, the BTEX plume will be significantly reduced in size and concentration. Under this scenario, model results show that it is unlikely that BTEX compounds would migrate more than 450 feet from the source area as measured from the northwest property boundary along Brookley Avenue. The maximum concentration within the dissolved BTEX plume should be reduced to approximately $10~\mu g/L$ after 13 years. Benzene concentrations should not exceed the DCRA target cleanup levels at the proposed POC well locations.

As discussed in Section 6.4.1, the effectiveness of this remedial alternative requires that excavations or drilling within the source area be conducted only by properly protected site workers. Reasonable land use assumptions for the plume area indicate that exposure is unlikely unless excavation or drilling activities bring contaminated soil to the surface. As with Alternative 1, long-term land use restrictions will be required.

Alternative 2 will satisfy program objectives designed to promote intrinsic remediation as a component of site remediation and to scientifically document naturally occurring processes. This alternative is based on the effectiveness of the bioventing system to remove residual LNAPL from the Car Care Center Site within a 5-year period. Once BTEX leaching rates are reduced, intrinsic remediation will then minimize contaminant migration and reduce contaminant mass in groundwater.

6.4.2.2 Implementability

Alternative 2 is not technically difficult to implement. As with Alternative 1, passive mobile LNAPL skimming will be used at the Car Care Center Site from four site monitoring wells. Bioventing systems have been operating at other sites on Bolling AFB, with favorable results. The bioventing system would consist of a series of air injection wells connected to a small blower by underground piping. This equipment is fairly common within the environmental industry. Because the alternative does not directly affect the residual LNAPL at the site, DCRA may not approve of bioventing as the primary source control measure for the site. Also, the oxygen demand may initially be too high to augment with bioventing alone due to the presence of high VOC concentrations in subsurface soils. As a result, bioventing may not provide adequate removal of the residual LNAPL at the site. During this evaluation, costs for pilot testing were provided to determine whether additional measures may be required to remove excessive residual LNAPL from the site.

During design of a bioventing system, caution should be taken to ensure that the air injection process will not force volatile hydrocarbon vapors into surrounding buildings

and sumps. Because numerous buildings exist within and adjacent to the Car Care Center, engineered controls must be provided to ensure health and safety of Base personnel and property. Due to the high VOC concentrations present in the subsurface, very low air injection rates may be necessary in order to control VOC migration. This may limit the effectiveness of the bioventing system, until VOC concentrations have been reduced.

6.4.2.3 Cost

The cost of Alternative 2 is summarized in Table 6.4. A more complete breakdown and present worth analysis of these costs are provided in Appendix F. Capital costs are limited to the construction of three new POC wells, one new LTM well, eight vent wells, eight vapor monitoring points, and the bioventing system. As with Alternative 1, passive mobile LNAPL removal is proposed for a period of 3 years. The bioventing system would operate for 5 years. LTM would continue for 13 years during bioventing system operation. The overall cost of passive mobile LNAPL removal, the bioventing system installation and operation, and implementation of the LTM plan is \$529,000 total present worth. Also included are the costs of maintaining institutional controls for a total of 13 years.

6.4.3 Alternative 3 - Passive Mobile LNAPL Removal, Soil Vapor Extraction with Off-Gas Treatment, Bioventing in Source Area, Intrinsic Remediation, and Institutional Controls with Long-Term Groundwater Monitoring

6.4.3.1 Effectiveness

An additional Bioplume II model (SR33) was performed to evaluate the effectiveness of source reductions associated with a SVE system in combination with bioventing, and passive mobile LNAPL removal. Model SR33 assumed source concentrations would be reduced at a rate of 33 percent of the original concentration every year for 3 years. Model results suggest that if SVE and bioventing were chosen as the remedial alternative, the BTEX plume would be significantly reduced in size and concentration. Under this scenario, BTEX plume reductions occur slightly faster than for bioventing and passive LNAPL skimming alone. Model results suggest that it is unlikely that BTEX compounds would migrate more than 425 feet from the source area, as measured from the property boundary along Brookley Avenue. The maximum dissolved BTEX concentration within the plume is reduced to approximately 100 µg/L after 11 years of treatment. Benzene concentrations should not exceed the DCRA target cleanup level at the proposed POC well locations. The effectiveness of this remedial alternative requires the same land use restrictions and institutional controls as discussed for Alternatives 1 and 2.

Alternative 3 will satisfy program objectives designed to promote intrinsic remediation as a component of site remediation and to scientifically document naturally occurring processes. This alternative is based on the effectiveness of the combined SVE and bioventing system to reduce residual BTEX concentrations within a 3-year period. The model predicts that after leaching rates are reduced, the intrinsic remediation processes will then minimize contaminant migration and reduce contaminant mass in the groundwater within 11 years.

Project Management (13 years)	\$3,120
Present Worth of Alternative 1 a/	\$529,000

^a Based on an annual adjustment factor of 5 percent.

See Appendix F for breakdown of costs and present worth analysis

6.4.3.2 Implementability

Alternative 3 is not technically difficult to implement. SVE and bioventing technology is easy to implement. As with Alternatives 1 and 2, passive mobile LNAPL skimming will be performed within four site monitoring wells. The conceptual SVE and bioventing system will consist of a series of air extraction and injection wells. For estimating purposes, five air extraction wells, three bioventing wells, and a total of eight vapor monitoring points were proposed. The SVE system would be powered by a small ICE unit, provided by AFCEE at no additional cost to the Base, which will treat the extracted VOCs in the soil gas. The provided estimate for Alternative 3 also includes costs for obtaining an air emission permit from DCRA. A small pressure blower will be required to power the bioventing system. Both the ICE unit and the blower will be connected to the air extraction/injection wells by underground piping. All required equipment is readily obtainable.

The SVE system would likely be operated for 6 to 12 months to remove the initially high excess VOC concentrations from the soil gas. Parsons ES assumed a 12-month duration for the purposes of this estimate. After that time, the SVE system would be dismantled and the bioventing system would be installed and operated for the remaining 2 years. This conversion period would depend on the ability of bioventing (alone) to sustain oxygenated conditions in the subsurface.

6.4.3.3 Cost

The cost of Alternative 3 is summarized in Table 6.5. A more complete breakdown and present worth analysis of these costs are provided in Appendix F. Necessary costs were included in this analysis to perform short-term pilot testing for the SVE and bioventing systems. Capital costs are limited to the construction of three new POC wells, three new LTM wells, eight vent wells, eight vapor monitoring points, the bioventing system, piping costs, and four passive skimmers. The ICE unit is already owned by the AFCEE. As a result, capital costs for the unit are not required. Transportation costs for the ICE unit were included. As with Alternatives 1 and 2, mobile LNAPL is proposed to continue for 3 years. The ICE is assumed to operate for the first year and the bioventing system is assumed to operate for the remaining 2-year period. LTM will initiate upon remedial system installation and continue for 11 years. The overall cost of passive LNAPL removal, the bioventing systems, remedial system installations, and implementation of the LTM plan is \$485,000 total present worth. Also included are the costs of maintaining institutional controls and long-term groundwater monitoring for a total of 11 years.

6.5 RECOMMENDED REMEDIAL APPROACH

Three remedial alternatives have been evaluated for remediation of the shallow groundwater at the Car Care Center Site. Components of the alternatives include intrinsic remediation with LTM, bioventing, and SVE using an ICE unit, and bioventing. Tables 6.2, 6.3, 6.4, and 6.5 summarize the results of the evaluation based upon effectiveness, implementability, and cost criteria. Table 6.6 summarizes the costs for the three selected alternatives. Alternative 1 may not be accepted by DCRA because it did not actively address the residual LNAPL remaining source area. Also, Alternative 2 may potentially affect adjacent buildings due to VOC migration in

² Alternative 3 was the selected remedial option.

the vadose zone. Based on these evaluations, the Air Force recommends Alternative 3 as achieving the best combination of risk reduction and cost effectiveness.

In October 1996, an ICE/SVE system was installed at the former Car Care Center. Using a V2 ICE unit, the ICE/SVE system ran from October 16 until October 20. During this time period the ICE/SVE unit removed 144 pounds of total volatile hydrocarbons (TVH) from the site's underlying soils. On October 20, the ICE/SVE system was shut down, because of extremely high TVH concentrations in the effluent. A larger ICE unit, a V4 model, is scheduled to replace the V2 ICE unit during the week on November 4, 1996. The startup and optimization of the model V4 ICE unit at the former Car Care Center is anticipated in mid November, 1996.

It is likely that natural attenuation alone (Alternative 1) will not accomplish the remedial objectives for the site, due to extensive residual LNAPL contamination at the Car Care Center Site. Based on all the effectiveness criteria, Alternative 3 will make maximum use of intrinsic remediation mechanisms to reduce plume migration and toxicity while providing the added benefits of enhanced in situ soil remediation in the source area and the introduction of additional oxygen (through infiltration and reaeration) into the groundwater. Implementation of Alternative 3 will require land-use and groundwater-use controls and semiannual groundwater monitoring for approximately 11 years after startup of the ICE system.

The final evaluation criterion used to compare each of the three remedial alternatives was cost. It is the opinion of the Air Force that the Alternative 3 is the most economical remedial alternative for the site. Because Alternative 3 is a more aggressive remedial approach, active remediation time frame is reduced to approximately 3 years and LTM is reduced to approximately 11 years, reducing the overall present value cost for this alternative, as compared to Alternatives 2 and 3.

SECTION 7

LONG-TERM MONITORING PLAN

7.1 OVERVIEW

In keeping with the requirements of the preferred remedial alternative for the Car Care Center Site (passive LNAPL recovery, SVE via an ICE system, bioventing, and intrinsic remediation with LTM), a long-term groundwater monitoring plan must be developed. The purpose of this component of the preferred remedial alternative for the site is to assess conditions over time; confirm the effectiveness of LNAPL recovery, SVE, bioventing, and naturally occurring processes at reducing contaminant mass and minimizing contaminant migration; and evaluate the need for additional remediation.

To demonstrate attainment with both levels of site-specific remediation goals and to verify the predictions of the Bioplume II model developed for the Car Care Center Site, the LTM plan consists of identifying the location of two separate groundwater monitoring networks and developing a groundwater sampling and analysis strategy. The strategy described in this section is designed to monitor plume migration over time and to verify that intrinsic remediation is occurring at rates sufficient to protect potential receptors. In the event that data collected under this LTM program indicate that naturally occurring processes (in addition to LNAPL recovery, SVE, and bioventing) are insufficient to protect human health and the environment, contingency controls to augment the beneficial effects of intrinsic remediation would be necessary.

7.2 MONITORING NETWORKS

Two separate sets of wells will be used at the site as part of the I TM program. The first set will consist of four LTM wells located in, upgradient, and downgradient of the observed BTEX plume to verify the results of the Bioplume II modeling effort and to ensure that natural attenuation is occurring at rates sufficient to minimize plume expansion (i.e., meet the first level of RAOs for the site). This network of wells will consist of existing and proposed wells screened within the shallow aquifer to provide short-term confirmation and verification of the quantitative groundwater modeling results. The second set of groundwater monitoring wells will be located approximately 700 feet downgradient from the source area (northwest property boundary along Brookley Avenue). The purpose of the POC wells is to verify that no BTEX compounds exceeding DCRA target cleanup values and federal MCLs migrate beyond the area under institutional control (i.e., meet the second level of RAOs for the site). This network will consist of three groundwater monitoring wells screened across the first 10 feet of the shallow aquifer. The LTM and POC wells will be sampled for analysis of the parameters listed in Tables 7.1 and 7.2, respectively.

7.2.1 Long-Term Monitoring Wells

Four groundwater wells within, upgradient, and downgradient of the existing BTEX contaminant plume will be used to monitor the effectiveness of intrinsic remediation in reducing total contaminant mass and minimizing contaminant migration at the Car Care Center Site. These wells will follow the contaminant flow path with one well located in each of the following areas: the anaerobic treatment zone, the aerobic treatment zone, and downgradient from the aerobic treatment zone.

At three locations, existing or replacement wells will be used for this purpose. Well MW-4R will be used to monitor conditions near the plume core, while CPT-22D will be used to monitor conditions in the aerobic treatment zone. Monitoring well MW-9 will be used for monitoring upgradient of the plume. One new well should be installed downgradient of the plume. Figure 7.1 identifies the proposed locations of the new well and the existing wells to be used for LTM. This network will supplement the POC wells to provide early confirmation of model predictions and to allow additional response time if necessary. The new LTM well will be constructed with a 10-foot screen, with approximately 8 feet of the screen below the water table. All LTM wells will be sampled and analyzed for the parameters listed in Table 7.1 to verify the effectiveness of the intrinsic remediation remedial alternative.

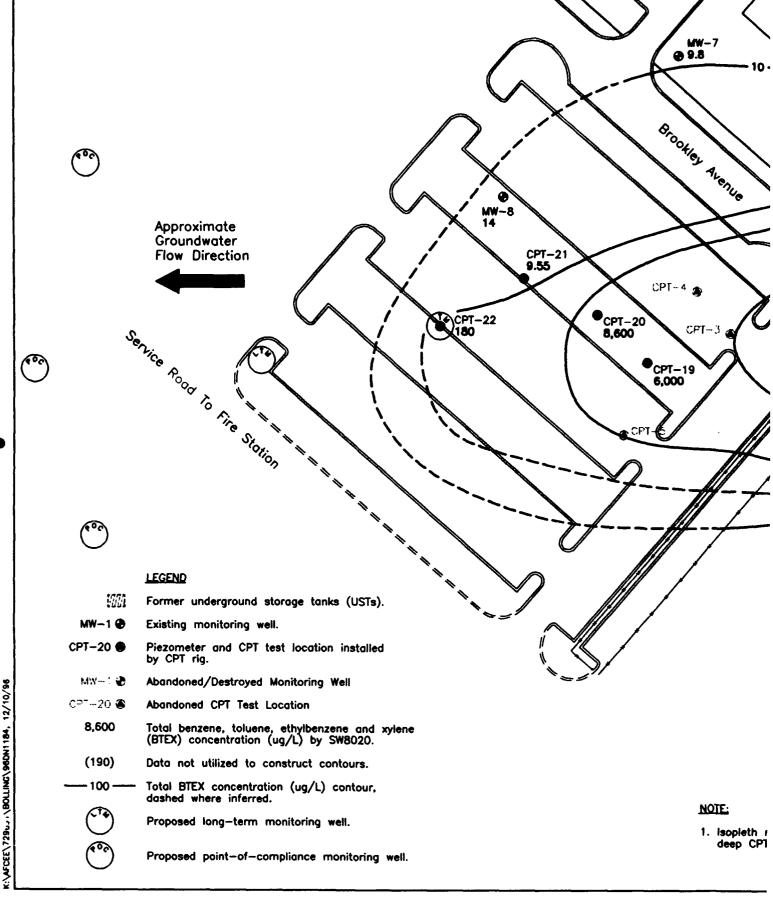

7.2.2 Point-of-Compliance Wells

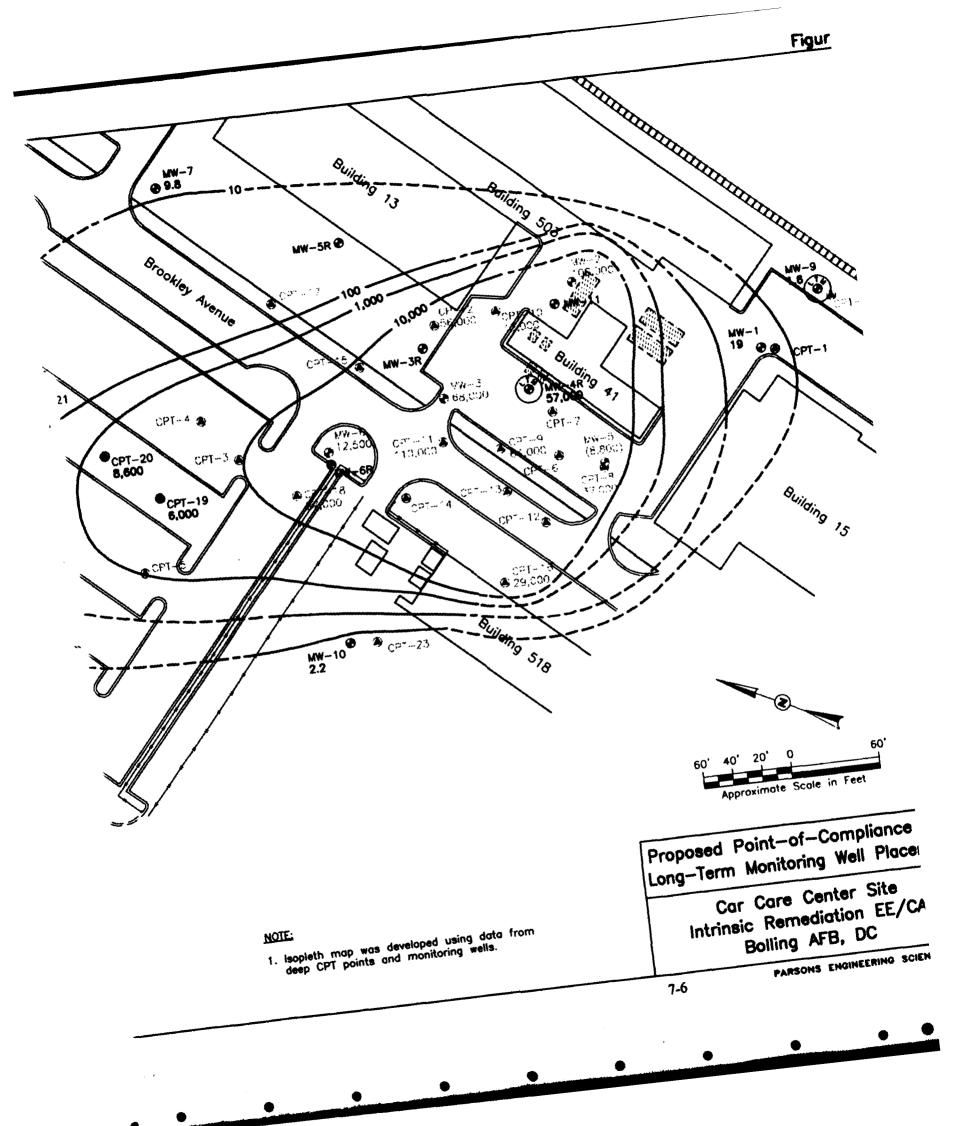

Three POC monitoring wells should be installed approximately 650 feet downgradient of the source area. Figure 7.1 shows the proposed locations of these wells. The purpose of the POC wells is to verify that no contaminated groundwater exceeding DCRA target cleanup values and federal MCLs migrates beyond the area under institutional control. Although model results suggest that the contaminant plume will not migrate beyond this location at concentrations exceeding chemical-specific federal MCLs, these POC wells are the technical mechanisms used to demonstrate protection of human health and the environment and compliance with site-specific numerical remediation goals. These wells will be installed and monitored for the parameters listed in Table 7.2 to assure that the selected remedy is providing the anticipated level of risk reduction and remediation at the site.

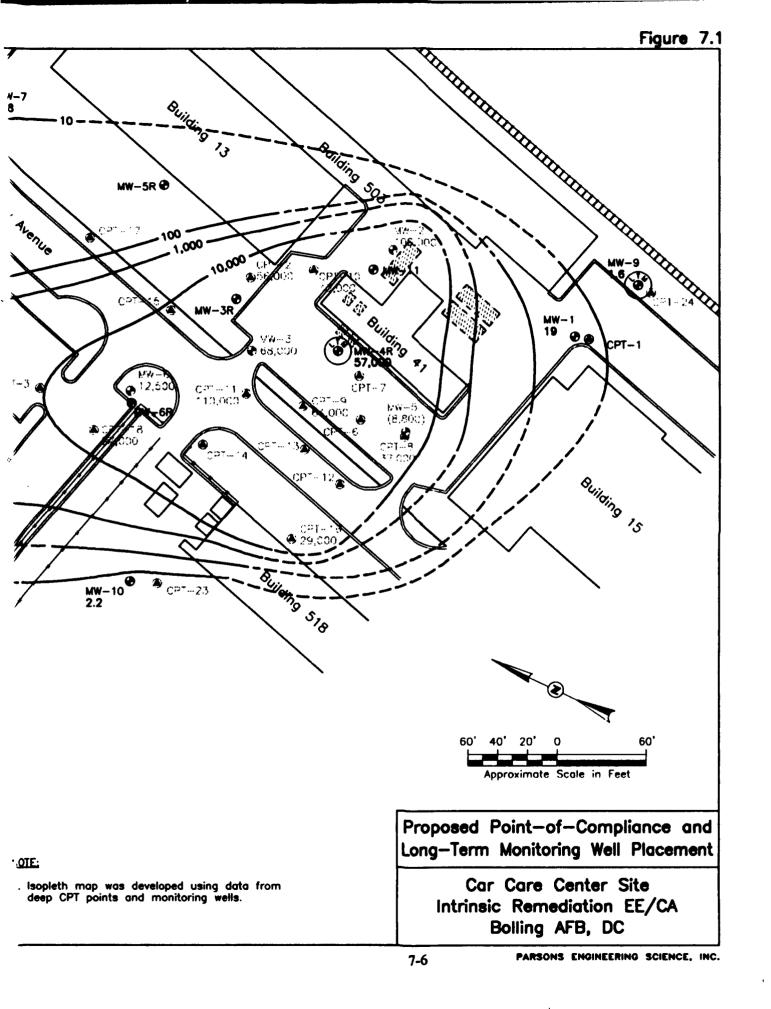

As with the LTM wells, the POC wells will also be screened in the same hydrogeologic unit as the contaminant plume. Data presented in this report concerning the nature and extent of contamination at the site suggest that a 10-foot screen with approximately 8 feet of screen below the groundwater surface will be sufficient to intercept the contaminant plume at this site. Figure 7.2 is a proposed groundwater monitoring well completion diagram for both the LTM well and the POC wells.

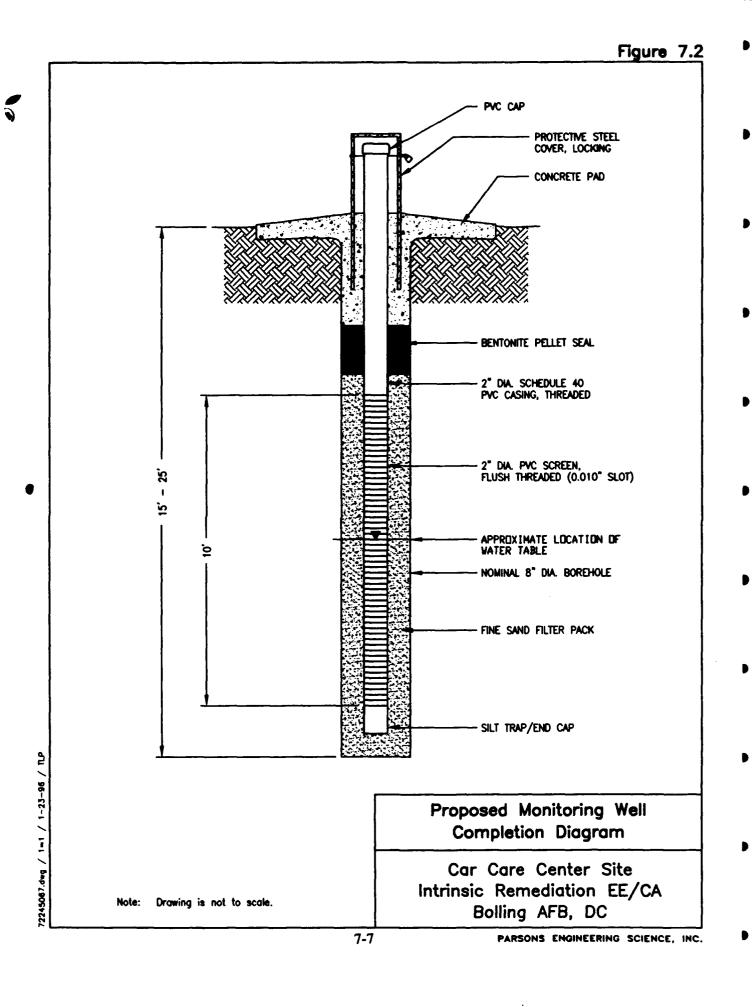

7.3 GROUNDWATER SAMPLING

To ensure that sufficient contaminant removal is occurring at the Car Care Center Site to protect human health and the environment and meet site-specific remediation goals, the long-term groundwater monitoring plan includes a comprehensive sampling and analysis plan. Both LTM and POC wells will be sampled and analyzed semiannually to verify that naturally occurring processes are effectively reducing contaminant mass and mobility. Reduction in toxicity will be implied by mass

reduction. The sampling and analysis plan will also be aimed at assuring that intrinsic remediation can achieve site-specific remediation concentration goals for BTEX compounds and protect human health and the environment.

7.3.1 Analytical Protocol

All LTM and POC wells in the LTM program will be sampled and analyzed to determine compliance with chemical-specific remediation goals and to verify the effectiveness of intrinsic remediation at the site. Water level measurements will be made during each sampling event. Groundwater samples will be analyzed for the parameters listed in Tables 7.1 and 7.2. A site-specific groundwater sampling and analysis plan should be prepared prior to initiating the LTM program.

7.3.2 Sampling Frequency

Each of the LTM and POC sampling points will be sampled twice each year for 11 years. If the data collected during this time period supports the anticipated effectiveness of the intrinsic remediation alternative at this site, the sampling frequency can be reduced to once every year for all wells in the LTM program, or eliminated. If the data collected at any time during the monitoring period indicate the need for additional remedial activities at the site, sampling frequency should be adjusted accordingly. Likewise, if the data collected during this period supports the anticipated effectiveness of intrinsic remediation, the sampling frequency can be reduced to once every year. The groundwater samples should be analyzed for BTEX compounds by USEPA Method SW8020. If BTEX concentrations in groundwater from the POC wells exceed the District of Columbia's target Cleanup levels of 5 microgram per liter (μg/L) for benzene, 1,000 μg/L for toluene, 700 μg/L for ethylbenzene, or 10,000 μg/L for total xylenes, additional corrective actions may be required to remediate groundwater at the site.

SECTION 8

CONCLUSIONS AND RECOMMENDATIONS

This report presents the results of a contaminant assessment conducted to evaluate the use of intrinsic remediation (natural attenuation) for remediation of fuel-hydrocarbon-contaminated groundwater at the Car Care Center Site (Building 41), Bolling AFB, DC. Specifically, the finite-difference groundwater model Bioplume II was used in conjunction with site-specific geologic, hydrologic, and laboratory analytical data to simulate the migration and biodegradation of fuel hydrocarbon compounds dissolved in groundwater. Groundwater contaminant and geochemical data collected in August 1994 and June 1996 strongly suggest that aerobic biodegradation of fuel hydrocarbons is occurring at the site. In addition, the data also suggest that anaerobic biodegradation is occurring via sulfate reduction, denitrification, iron and manganese reduction, and methanogenesis.

To evaluate intrinsic remediation, Parsons ES collected and analyzed soil and groundwater samples from the site. Physical and chemical data collected under this program were supplemented with data collected during previous site characterization events. Site-specific geologic, hydrogeologic, and laboratory analytical data from August 1994 were then used in the Bioplume II numerical groundwater model to simulate the effects of advection, dispersion, sorption, and biodegradation on the fate and transport of the dissolved BTEX plume. Extensive site-specific data were used for model implementation. Model parameters that could not be obtained from existing site data were estimated using widely accepted literature values for sediments similar to those found at the site. Conservative aquifer parameters were used to construct the Bioplume II model for this study.

For one simulation (model CAL2), it was assumed that BTEX compounds will continue to enter the aquifer at a constant rate. That rate was the same rate used to produce the initial calibrated model. Predictions based on model CAL2 show that the BTEX plume equilibrates after 25 to 30 years, with the leading edge of the plume stabilizing approximately 460 feet beyond the Car Care Center property boundary along Brookley Avenue. For a second simulation (model SR20), it was assumed that BTEX loading rates were significantly decreased by bioventing over a 5-year period. A third simulation (model SR33), assumed that BTEX loading rates were decreased over a 3-year period by a combination of SVE, and bioventing technologies. Results of the SR20 and SR33 models represent optimistic scenarios in which dissolved BTEX compounds would degrade to below detectable concentration in 13 years or less.

Groundwater data collected in June 1996 allows for the direct comparison of observed contaminant plume migration and predicted model results. Even though no active remediation has occurred since the August 1994, the observed dissolved BTEX

plume in June 1996 (Figure 4.4) indicates that source area concentrations have decreased while the leading edge of the plume has migrated slightly to the northwest. Both the slight decrease in source area concentrations and the minimal northwesterly migration of the leading edge of the June 1996 BTEX plume are very similar to the predicted 1996 plume assuming no source removal. Using several points for comparison, the observed increase in dissolved contamination near the leading edge of the plume, in June 1996, seems to slightly exceed model predictions for the downgradient migration distance of the 10,000 μ g/L, 1,000 μ g/L, and 100 μ g/L isopleths for 1996. However, groundwater data collected in June 1996 continue to suggest that several natural attenuation processes are decreasing source area concentrations of dissolved BTEX contamination and limiting plume migration.

The results of this study suggest that natural attenuation of BTEX compounds is occurring at the Car Care Center Site to the extent that the dissolved concentrations of these compounds in groundwater should be reduced to levels below current regulatory guidelines long before potential downgradient receptors could be adversely affected (i.e., the potential contaminant migration pathway will not be complete for any of the potential receptors described in Section 6.2). However, the Air Force has recommended a more aggressive remedial option consisting of SVE and bioventing system in combination with passive LNAPL removal, natural attenuation, institutional controls, and LTM at the Car Care Center Site. This alternative would address the source of contamination and reduce cleanup times while remaining cost-effective. To accomplish this recommendation, construction activities and groundwater use in and downgradient from the source area should be restricted for a period of approximately 11 years or until groundwater contaminant concentrations decrease below DCRA target cleanup values. Groundwater samples should be collected on an semiannual basis during LTM to monitor plume migration, allowing continual reevaluation of the proposed remedial time frame.

In October 1996, the first component of the preferred remedial alternative was implemented through installation of an ICE/SVE system at the former Car Care Center. Using a V2 ICE unit, the ICE/SVE system ran from October 16 until October 20. During this time period the ICE/SVE unit removed 144 pounds of total volatile hydrocarbons (TVH) from the site's underlying soils. On October 20, the ICE/SVE system was shut down, because of extremely high TVH concentrations in the effluent. A larger ICE unit, a V4 model, replaced the V2 ICE unit during November 1996.

With the implementation of a new source removal technology, i.e. SVE system, the dissolved contaminant plume is expected to decrease significantly within the next two years (the expected running time of SVE operations). SVE operations are expected to significantly decrease TVPH concentrations in source area soils by 1998, which in turn should reduce the dissolution of additional fuel constituents to groundwater and consequently limit the migration of water soluble fuel hydrocarbons in the site groundwater. Results from future monitoring of the dissolved BTEX plume are anticipated to show more rapid decrease in contamination than CAL2 model predictions and perhaps comparable to model predictions for the 20 to 33 percent annual source removal scenarios.

To verify the results of the Bioplume II modeling effort and the implemented remedial option, and to ensure that natural attenuation is occurring at rates sufficient to

8-2

protect potential downgradient receptors, groundwater from three existing monitoring wells, one proposed LTM well, and three proposed POC wells should be sampled semiannually and analyzed for the parameters listed in Tables 7.1 and 7.2. The three POC groundwater monitoring wells will be installed downgradient from the predicted maximum travel distance of the BTEX plume, at approximately 650 feet downgradient of the source area. If dissolved BTEX concentrations in the POC wells are found to exceed the federal MCL and DCRA target cleanup values of 5 μ g/L for benzene, 1,000 μ g/L for toluene, 700 μ g/L for ethylbenzene, or 10,000 μ g/L for total xylenes, additional evaluations or corrective actions may be necessary at this site.

Data Report : 94-2981 Client Project : Bolling AFB

Dear Ms. Saxton:

Enclosed are the analytical results for the samples shown in the Sample Log Sheet. The enclosed data have been reviewed for quality assurance. If you have any questions concerning the reported information, please contact Mark Mensik, Project Manager, or me.

Please Note: Samples marked for return on the Sample Log Sheet are considered hazardous, unsuitable for municipal disposal or were placed on hold at your request. Samples considered hazardous or unsuitable for municipal disposal will be returned to you immediately. Samples placed on hold will be returned and samples not considered hazardous will be disposed of one (1) month from the date of this letter.

The invoice for this work will be mailed to your Accounts Payable department shortly.

Thank you for using the services of Evergreen Analytical.

Sincerely,

Jack Barney President

JJ

CASE NARRATIVE

Evergreen Analytical Project #: 94-2981

Engineering Science, Inc. (BS) Project: Bolling AFB (722450.02)

Sample Receipt

On August 8, 10, 11 and 12, 1994, 17 soil samples, 31 water samples and one free product sample were received in good condition at Evergreen Analytical Laboratory (EAL). Samples SB-14(14'BLS) and SB-14(20'-21'4") were mislabelled on the chain-of-custody (coc) as SB-14(14'-14'8") and SB-14(14'8"-15'4"), respectively. This was confirmed by Todd Wiedemeier of ES to Mark Mensik of EAL, and has been noted on the coc and the EAL Check-in Record. Refer to the EAL Sample Log Sheet for specific log-in information and cross-reference of EAL and ES sample identifications.

BTEX. Soil Matrix. Method 8020 There were no quality control anomalies to report.

Samples SB14(20'-21'4"), SB7(10'9"-11'5"0) and SB3(22'-24'5") were initially analyzed at dilution factors of 1250, 1250 and 125, respectively, due to suspected high levels of contamination. Analysis of these samples confirmed the suspected high level of background contamination. These samples were not reanalyzed at a lower dilution because the high background contamination most likely would have swamped the detector and possibly shut down the instrument. Thus, the practical quantitation limit (PQL) reported for these samples is 6000, 6000 and 560 μ g/Kg, respectively (after adjustment for *moisture*). Several of the compound concentrations were less than the PQL and have been flagged as estimated (J). Other compounds were non-detected and have been flagged "U", indicating the compound was not detected at or below the associated method detection limit, which is a factor of 10 lower than the PQL.

BTRX. Trimethylbenzene Isomers. Water Matrix. Method 8020 The water samples for BTRX and Trimethylbenzene isomers were analyzed using SW846 Method 8020. The data reports indicate a PQL of 4.0 μ g/L. The method detection limit (MDL) for waters by this method is 0.4 μ g/L. All results reported as non-detected are done so using the qualifier "U". All results reported as non-detected (U) are considered non-detected at the MDL. Additionally, results reported as detected above the MDL but less than the PQL are qualified as estimated and flagged with a "J".

The trip blanks were not analyzed since the coc requested they be held.

Page 2 Case Narrative EAL Project #94-2981

Total Volatile Hydrocarbons-Gasoline (TVH). Method 8015 Modified There were no quality control anomalies to report.

Total Organic Carbon

Total organic carbon (TOC) was analyzed by Huffman Laboratories of Golden, Colorado. TOC was determined by analyzing for total carbon (TC) and inorganic (carbonate) carbon (CC), then calculating the difference as TOC. The report from Huffman is included. The other sample on the report is from the ES Carswell APB project.

Methane

Methane was analyzed using a modified version of a draft method provided by ES. The method, identified as RSKSOP-147, is described below:

Water samples were collected in 40ml VOA vials. A 10ml volume was removed to create headspace. The samples were then heated at 105°F, for a minimum of 30 minutes, to liberate any methane present. A sample of the headspace was drawn out of the vial through the septum with a 500 μ l air tight syringe and injected into the GC.

Since only one bottle was received for this analysis, samples were screened during the removal of the 10ml of sample to determine the sample injection volume. "Clean" samples were run with a full 500 μ l injection volume. Other samples were run at either 100 or 50 μ l injection volumes. Injection volumes below 50 μ l are not accurate so some samples may have been under diluted.

Given the limited sample volume and the syringe limitations, every attempt was made to perform the analysis as consistently as possible from sample to sample, and to provide usable, reliable data.

Alkalinity, Method 310.1

There were no quality control anomalies to report.

Anions (Nitrate as N. Sulfate) Method 300.0 There were no quality control anomalies to report.

Samples CPT-18S, CPT-18D and MW-2 were received at EAL after the holding time of 48 hours had expired for the analysis of nitrate as N. The results are reported as Nitrite + Nitrate as N. All other nitrate as N results were analyzed within holding time.

Mark J. Mersik, Project Manager

Evergreen Analytical Sample Receipt/Check-in Record
Date & Time Rec'd: 8/08/94 08.30 Shipped Via: Ver (Airbill # if applicable)
client: <u>Lngineering</u> Science
Client Project ID(s): Bolling AfB, 422450.08020
EAL Project #(s):94- EAL Cooler(s): Y N
cooler# 307
Ice packs (Y) malted y N Y N Y N Y N
Temperature & 19.7
Y N N/A
1. Custody seal(s) present: Seals on cooler intact Seals on bottle intact
2. Chain of Custody present:
3. Containers broken or leaking: (Comment on COC if Y)
4. Containers labeled:
5. COC agrees w/ bottles received: (Comment on COC if N) A direct two Samples lasted (COC agrees w/ labels: (COC agrees w/ labels:
6. COC agrees w/ labels: (Comment on COC if N)
7. Headspace in VOA vials-waters only
8. VOA samples preserved:
9. pH measured on metals, cyanide or phenolics*:
10. Metal samples present:
Total, Dissolved
D or PD to be filtered:
11. Short holding times: Specify parameters
12. Multi-phase sample(s) present:
13. COC signed w/ date/time: On coc is ectual
comments: Per Told W. to MIM B/8 @ 1500: SB-14(14'-14'8") should be the samples (cceined labelled as SB-14(14'BLS) and SB14(14'8"-15'4") NIM
on coc is actually sample sociled labelled as SB-14 (20-214").

DATA OUALIFIERS

- E = Extrapolated value.
- U = Compound analyzed for, but not detected.
- B = Compound found in blank and sample. Compare blank and sample data.
- J = Indicates an estimated value when the compound is detected, but is below the Practical Quantitation Limit (PQL).
- PQL = Practical Quantitation Limit. The PQL is equal to the dilution factor multiplied by ten times the Method Detection Limit as determined by EPA SW846, Vol. 1B, Part II, pa. 8000-14.
- NA = Not available.

Client Sample Number : MW-3(Free Product) Client Project No. : Bolling AFB Lab Sample Number : X92398 Lab Project No. : 94-2981 **Date Sampled** : 8/9/94 Dilution Factor : 500000 Method **Date Received** : 8/10/94 : 8020 Date Extracted/Prepared Matrix : 8/24/94 : Product Date Analyzed : 8/24/94 Lab File No. : BX1082413 Methanol Extract : Yes Method Blank No. : MEB082494

Compound Name	Cas Number	Concent	Sample Concentration %	
Benzene	71-43-2	0.3		0.2
Toluene	108-88-3	4.5	В	0.2
Ethyl Benzene	100-41-4	1.3		0.2
Total Xylene (m/p + o)	1330-20-7	7.7	В	0.2
Total BTEX		13.8		

Note: Total Xylene consist of three isomers, two of which co-elute.

The Xylene PQL is for a single peak.

Surrogate Recovery:

a,a,a,-Trifluorotoluene : 111%
QC Reporting Limits : 55%-127%

QUALIFIERS:

E = Extrapolated value

U = Compound analyzed for, but not detected.

B = Compound found in blank and sample. Compare blank and sample data.

J = Indicates an estimated value when the compound is detected, but is below the Practical Quantitation Limit (PQL).

PQL = Practical Quantitation Limit. The PQL is equal to the dilution factor multiplied by ten times the Method Detection Limit as determined by EPA SW846, Vol. 1B, Part II, pa. 8000-14.

NA = Not available

Total Xylene (m/p + o)	1330-20-7	22000	560

Note: Total Xylene consist of three isomers, two of which co-elute.

The Xylene PQL is for a single peak.

Surrogate Recovery:

a,a,a,-Trifluorotoluene : 87% QC Reporting Limits : 55%-127%

QUALIFIERS:

** = All sample results and PQLs are reported on a dry weight basis.

E = Extrapolated value

U = Compound analyzed for, but not detected.

B = Compound found in blank and sample. Compare blank and sample data.

J = Indicates an estimated value when the compound is detected, but is below the Practical Quantitation Limit (PQL).

PQL = Practical Quantitation Limit. The PQL is equal to the dilution factor multiplied by ten times the Method Detection Limit as determined by EPA SW846, Vol. 1B, Part II, pa. 8000-14.

NA = Not available.

Data Report : 95-0313 Client Project : BOLLING AFB

Dear Mr. Wiedemeier:

Enclosed are the analytical results for the samples shown in the Sample Log Sheet. The enclosed data have been reviewed for quality assurance. If you have any questions concerning the reported information, please contact Carl Smits, Vice President of Quality Assurance, or me.

Please Note: Samples marked for return on the Sample Log Sheet are considered hazardous, unsuitable for municipal disposal or were placed on hold at your request. Samples considered hazardous or unsuitable for municipal disposal will be returned to you immediately. Samples placed on hold will be returned and samples not considered hazardous will be disposed of one (1) month from the date of this letter.

The invoice for this work will be mailed to your Accounts Payable department shortly.

Thank you for using the services of Evergreen Analytical.

Sincerely,

Jack Barney

President

CASE NARRATIVE

Evergreen Analytical Laboratory (EAL) Projects: 96-1794, 96-1796

Parsons Engineering Science, Inc. (PES) Project : Bolling AFB

729691.08110

Sample Receipt

Groundwater samples were received on June 1 and 3, 1996 at EAL for analysis under subcontract 722450.SC02. Refer to the EAL Check-in Record for specific information regarding the condition of samples upon receipt. Refer to the EAL Work Order Summary for specific log-in information and cross-reference of EAL and PES sample identifications.

Data Package

All data are reported in one comprehensive package that is segregated based upon EAL project number. Each EAL project represents a group of samples received on a given day. The EAL Sample Work Order summarizes the samples represented in each EAL project.

A separate invoice for each EAL project number will be generated.

Quality assurance data may overlap from one EAL project to another. All required matrix spike/matrix spike duplicate (MS/MSD) and laboratory control samples (LCS) were analyzed when required and also are included in the data package.

BTEX, Method SW8020/Total Volatile Hydrocarbons TVH, Method SW8015M All samples were analyzed for BTEX/TVH within holding time.

Several samples were analyzed at dilutions ranging from a dilution factor of 10 to 500 due to elevated levels of contaminants of interest. The reporting limits have been adjusted accordingly.

There are no quality control anomalies to report.

Case Narrative Parsons Engineering Science, Inc. Page Two

Methane, Method RSKSOP175M

All samples submitted for Methane analysis were analyzed within holding time.

Several samples were analyzed at dilutions ranging from a dilution factor of 50 to 100 due to elevated levels of methane present. The reporting limits were increased accordingly.

There are no quality control anomalies to report.

General Chemistry

There were no quality control anomalies to report for Anions by Method 300.0 or Alkalinity by Method 310.1 with the following exception: samples for NO₂ and NO₃ analysis received on June 3 in EAL project 96-1796 were received outside of holding time. The instructions on the chain of custody indicated to analyze regardless.

Disk Deliverables

The disk deliverables are included with the hard copy data package. MS/MSD and laboratory duplicate samples are not included on the disk. A PES requested duplicate for sample 20S BTEX/TVH is included on the disk. Please note that blank spaces in the laboratory detection limit and/or practical quantitation limit (PQL) column indicate that there is no detection limit or PQL for that analyte.

A hard copy of each spreadsheet from the diskette is included. The name for each spreadsheet is located in the top left corner of the first page of each printout.

QUALIFIERS and DEFINITIONS:

E = Extrapolated value. Value exceeds calibration range.

U = Compound analyzed for, but not detected.

B = Compound also found in the blank.

J = Indicates an estimated value when the compound is detected, but is below the Reporting Limit.

RL = Reporting Limit.

NA = Not Available/Not Applicable.

PID = Photoionization detector.

FID = Flame ionization detector.

TVH = Total Volatile Hydrocarbons.

Notes: Total Xylenes consist of three isomers, two of which co-elute. The Xylene RL is for a single peak.

Comments:		
	 	

QUALIFIERS and DEFINITIONS:

- **E** = Extrapolated value. Value exceeds calibration range.
- **U** = Compound analyzed for, but not detected.
- **B** = Compound also found in the blank.
- J = Indicates an estimated value when the compound is detected, but is below the Reporting Limit.
- RL = Reporting Limit.
- NA = Not Available/Not Applicable.
- **PID** = Photoionization detector.
- FID = Flame ionization detector.
- TVH = Total Volatile Hydrocarbons.

APPENDIX D8 ESTIMATION OF LONGITUDINAL DISPERSIVITY

Assumptions: A. Plume migration is sufficiently aligned along the longitudinal axis of the grid to calculate a longitudinal moment.

B. Longitudinal dispersivity is 1/10 of the distance from the contamination source to the center of contamination.

From Appendix D2, an estimate for the center of mass will be taken by calculating the longitudinal moment around cell (10,3) which is near the source of contamination.

		Distance From	
	Mass	Cell (10,3)	Mass x Distance
Row	(u g/ l)	(ft)	(ug-ft/L)
2	0	35	0
3	0	70	0
4	30	105	3,150
5	245	140	34,300
6	1,880	175	329,000
7	34,510	210	7,247,100
8	350,385	245	85,844,325
9	89,418	280	25,037,040
10	87,985	315	27,715,275
11	97,360	350	34,076,000
12	73,875	385	28,441,875
13	63,995	420	26,877,900
14	51,075	455	23,239,125
15	26,155	490	12,815,950
16	19,648	525	10,315,200
17	15,203	560	8,513,680
18	5,555	595	3,305,225
19	2,450	630	1,543,500
20	1,230	665	817,950
21	310	700	217,000
22	30	735	22,050
23	0	770	0
24	0	805	0
25	0	840	0
26	0	875	0
27	0	910	0
28	0	945	0
29_	0	980	0
Totals:	921,339		296,395,645

Now, estimate the longintudinal centroid of the plume:

 $\Sigma(\text{mass x distance})/\Sigma(\text{mass})$ in feet: 320 Estimated distance from cell (10,3) to the centroid in feet: 150 Estimated Longitudinal Dispersivity (Dist. x 0.1) in feet: 15
